54 Time stamping for packet system nodes.

67 Delay that a packet experiences in a network node is measured by employing a single local time signal in the node, and by separating a time stamp update function into a network node entry time stamp function and a network node exit time stamp function. The node entry time stamp function is to generate (via 208) a packet originate time value referenced to the local time signal value upon the packet entering the node. This packet originate time value is inserted (via 208) into a

packet header time stamp field to be transported through the node. The node exit time stamp function is to generate an updated time stamp value (via 1109) from the packet originate time value from the header time stamp field and the local time signal value upon the packet exiting the node. The updated time stamp value is inserted (via 1106, 1107) into the packet header time stamp field in place of the packet originate time value.

TIME STAMPING FOR PACKET SYSTEM NODES

Technical Field

This invention relates to packet transmission and/or switching networks and, more particularly, to an arrangement for determining the random delay experienced by packets as they progress through the transmission and/or switching networks.

Background of the Invention

The transmission of low bit rate voiceband signals utilizing packets, while offering the prospects of significant savings in transmission and switching costs over circuit switching, has not as yet been widely used because of problems encountered in transmitting and switching encoded voiceband information via packets. One of these problems has been the random delay experienced by the packets as they progress through the transmission and/or switching network. The random delay is introduced in multiplexing and switching nodes of the network because of the queuing of packets in buffer storage units prior to transmission or switching. Unlike data, voiceband information must be decoded at a substantially fixed rate in order to maintain quality voiceband signal reconstruction. The introduction of a random delay as the packets progress through the transmission and switching networks does not allow for proper decoding unless some compensation is provided for the random delay. In order to provide this compensation, the delay must be accurately determined.

One advantageous way of providing a measure of the random delay experienced by packets as they progress through a packet switching network is the so-called time stamp arrangement disclosed in U.S. patent 4,506,358 issued to W. A. Montgomery on March 19, 1985. This

prior time stamp arrangement requires the use of two packet header fields associated with updating the time stamp value in a packet network node. A first field contains the so-called received time stamp value upon  
5 entering the network node and the second field is used to carry the so-called packet arrival time through the network node. Upon exiting the network node, the values in time stamp field and the packet arrival time field are combined with a local timing signal value to obtain  
10 a new updated time stamp value. The calculation of the updated time stamp value is performed entirely upon exiting the network node which requires the use of the two header fields. The use of the additional arrival time field is undesirable because it requires additional  
15 equipment and control, and uses additional signal bandwidth.

#### Summary of the Invention

These and other problems of prior time stamp arrangements are overcome, in accordance with an aspect  
20 of the invention, by uniquely separating the time stamp value update function into a network node entry time stamp function and a network node exit time stamp function.

The network node entry time stamp function is  
25 to insert a so-called packet originate time value into a single time stamp field in the packet header. The packet originate time is referenced to a local time signal. Specifically, the packet originate time is equal to the local time upon the packet entering the  
30 network node as determined from the local time signal less the time stamp value from the packet header time stamp field. If the packet is being originated at the network node, the time stamp value from the packet header is zero and the packet originate time is the  
35 local time at which the packet is originated. The exit time stamp function is to insert an updated time stamp value into the time stamp field of the packet header in

place of the packet originate time upon the packet exiting the network node. The updated time stamp value is the local time value upon the packet exiting from the network node as determined from the local time signal less the value of the packet originate time from the time stamp field of the packet header. Both the entry and exit time stamp functions use the same local timing signal.

Brief Description of the Drawing

- 10           The invention will be more fully understood from the following detailed description of an illustrative embodiment taken in connection with the appended figures in which:
- 15           FIG. 1 shows a packet network including access interface transmitters and receivers including an embodiment of the invention;
- FIG. 2 depicts details of transmit access modules 106 employed in the access interface transmitter 101 of FIG. 1;
- 20           FIG. 3 illustrates a  $\mu$ -law PCM signal format and a corresponding packet information field format useful in describing the invention;
- FIG. 4 illustrates a 32-kilobit/s ADPCM signal format and a corresponding packet information field format in accordance with an aspect of the invention;
- 25           FIG. 5 depicts a packet header format useful in describing the invention;
- FIG. 6 is a flow chart illustrating a sequence of operations effected in controller 207 in controlling encoder 204 of FIG. 2;
- 30           FIG. 7 is a flow chart illustrating another sequence of operations effected in controller 207 in controlling packet assembler 202 of FIG. 2;
- FIG. 8 shows in simplified block diagram form details of bus controller 107 of FIG. 1;
- 35

FIG. 9 depicts a state diagram illustrating operations effected in input controller 801 in bus controller 107 of FIG. 8;

5      FIG. 10 shows a state diagram illustrating operations effected in output controller 803 in bus controller 107 of FIG. 8;

FIG. 11 depicts in simplified block diagram form details of transmit process modules 109 of access interface transmitter 101 of FIG. 1;

10      FIG. 12 shows a state diagram illustrating operations effected in input controller 1102 in transmit process modules 109 of FIG. 11;

FIG. 13 is a flow chart of a sequence of operations also effected in input controller 1102 of transmit process modules 109 of FIG. 11;

15      FIG. 14 shows a state diagram of operations effected in output controller 1106 in transmit process modules 109 of FIG. 11;

FIG. 15 depicts in simplified block diagram form details of receive process modules 113 of access interface receiver 102 of FIG. 1;

20      FIG. 16 shows a state diagram illustrating a sequence of operations effected in input sequencer 1506 in receive process modules 113 of FIG. 15;

25      FIGs. 17 and 18 show state diagrams of operations effected in output controller 1508 in receive process modules 113 of FIG. 15;

FIG. 19 depicts in simplified block diagram form details of receive access modules 116 of access interface receiver 102 of FIG. 1;

30      FIG. 20 is a flow chart of a sequence of operations effected in sequence number processor 1906 in receive access modules 116 of FIG. 19;

FIG. 21 is a flow chart of a sequence of operations effected by control logic in packet originate time (POT) processor and buildout delay register 1907 in receive access modules 116 of FIG. 19;

FIG. 22 shows a state diagram illustrating operations effected in receive packet bus sequencer 1910 in receive access modules 116 of FIG. 19;

FIG. 23 depicts a state diagram illustrating operations effected in ATS sequencer 1910 in receive access modules 116 of FIG. 19;

FIG. 24 illustrates delays experienced by packets in transmission and the playing out of such packets in access interface receiver 102;

FIG. 25 shows in simplified block diagram form details of encoder 204 used in transmit access modules 106 of FIG. 2;

FIG. 26 shows a state diagram illustrating operation of aspects of encoder 205;

FIG. 27 depicts in simplified block diagram form details of decoder 1902 used in receive access modules 116 of FIG. 19; and

FIG. 28 shows a state diagram illustrating operation of aspects of decoder 1902.

## Detailed Description

### General Description

FIG. 1 shows in simplified block diagram form an interface for accessing a packet network from a plurality of digital lines. The signals on the digital lines may include voice, digital data, voiceband data and the like, i.e., any of the signals transmitted, in this example, in the DSL format. Accordingly, shown are access interface transmitter 101 and access interface receiver 102 which interface with packet network 103.

It will be apparent to those skilled in the art that in practice an access interface receiver 121, essentially identical to receiver 102, is associated or otherwise co-located with each access interface transmitter 101 and an access interface transmitter 122, essentially identical to transmitter 101, is associated or otherwise co-located with each access interface receiver 102.

Although only an end-to-end arrangement is shown, it

will be apparent that a packet network may include numerous nodes through which packets will be transmitted and/or switched prior to being received at a particular access interface receiver.

- 5           Access interface transmitter 101 receives on transmission lines 104-1 through 104-N digital signals in, for example, a standard DSL format including voice, voiceband data and the like and converts those signals into packets for transmission. A plurality of time
- 10 division multiplexed signals are supplied by input terminals 104-1 through 104-N to digital line interface units (DLI) 105-1 through 105-N in access interface transmitter 101. The digital line interface units 105
- 15 DSL digital signals. Such digital line interface units include a phase locked loop for recovering the DSL clock signal of 1.544 Mb/sec, a bipolar-to-unipolar converter, an equalizer for the equalization of gain and/or delay distortion, performance monitoring apparatus, provision
- 20 for DSL loopback maintenance and apparatus for reformatting the unipolar digital signals from the 24 channel format into a 32 time slot PCM format having a first transmission rate, in this example, of
- 25 2.048 Mb/sec synchronous with the access interface internal timing. Although only 24 time slots are used to transmit data in this example, it will be apparent that all 32 time slots may be employed in other arrangements. The 32 time slot PCM output signals from DLIs 105-1 through 105-N are supplied to transmit access
- 30 modules 106-1 through 106-N, respectively. Each of transmit access modules 106 converts the 32 time slot PCM signals at the first transmission rate from associated ones of DLIs 105-1 through 105-N into a packet format in a manner as will be described below.
- 35 Bus controller 107 interacts with each of transmit access modules 106-1 through 106-N and transmit packet bus 108 to control supplying packet outputs from

transmit access modules 106 to transmit packet bus 108  
The packets supplied to transmit packet bus 108 from  
each of transmit access modules 106-1 through 106-N  
include an internal destination code that identifies one  
5 of the transmit process modules 109-1 through 109-M in  
which the particular packet is intended to be processed.  
Transmit packet bus 108 has a processing rate, in this  
example, of 8.192 Mb/s. It should be noted that the  
number M of transmit process modules 109 may be more or  
10 less than the number N of transmit access modules 106.

Each transmit process module (109-1 through  
109-M) monitors transmit packet bus 108 to detect and  
obtain individual packets assigned to it. Each of  
transmit process modules 109 further processes its  
15 assigned packets to complete the packet header field and  
to provide buffering to realize a uniform output rate.  
Details of transmit process modules 109 are further  
described below. The packet outputs from transmit  
process modules 109-1 through 109-M are supplied to  
20 digital line interface (DLI) units 110-1 through 110-M,  
respectively. The DLI units 110-1 through 110-M each  
converts the packetized information into a digital  
output signal format. In this example, the digital  
output signal comprises the known extended PCM framing  
25 format wherein each frame includes 193 bits and is  
transmitted at the 1.544 Mb/s rate. Such line interface  
units are known in the art. The packetized  
DS1 formatted signals, including the packets of  
information, are supplied from DLI units 110-1 through  
30 110-M to packet network 103. Packet network 103 may be  
any of those known in the art. See, for example, U.S.  
patent 4,494,230, issued January 15, 1985 to  
J. S. Turner, for one example of a preferred packet  
switching network. The packetized DS1 signals are  
35 transmitted as desired to any number of remote access  
interface receiver units 102. Timing signals for the  
access interface transmitter 101 are derived from a

corresponding access interface receiver 121 co-located with the transmitter 101 for use in well-known fashion as desired. Local timing unit 119 generates the local timing signals used in operating the modules in

- 5 transmitter 101. The clock signal from which the local timing signals are derived is obtained from co-located access interface receiver 121 and will be described in relationship to access interface receiver 102.

- Access interface receiver 102 receives on
- 10 transmission lines 111-1 through 111-Y packetized digital signals in a DSI extended framing format from packet network 103 and converts those packetized digital signals to the standard DSI format including voice, voiceband data and the like. It is again noted that a
- 15 particular access interface receiver 102 may receive packets from one or more access interface transmitters 101 and the number Y of receive transmission lines may vary from receiver to receiver. To this end, the packetized signals are supplied via
- 20 DSI level transmission lines 111-1 through 111-Y to digital line interface (DLI) units 112-1 through 112-Y, respectively. Digital line interface units 112 are again of a type well known in the art which convert the bipolar DSI packetized signals into unipolar digital
- 25 signals, reformats the unipolar digital signals into a 32 time slot unipolar format having a transmission rate, in this example, of 2.048 Mb/sec, and recovers the DSI clock signal, etc. The recovered clock signal is employed in well-known fashion to generate the so-called
- 30 local timing signals in local timing unit 120 that are used in access interface receiver 102 and in a co-located access interface transmitter 122. Access interface transmitter 122 is essentially identical to access interface transmitter 101. The 32 time slot
- 35 unipolar packetized signals are supplied from each of DLIs 112-1 through 112-Y to receive process modules 113-1 through 113-Y, respectively. Each of

receive process modules 113-1 through 113-Y converts the incoming 32 time slot packetized signals from a first transmission rate into an internal processing rate employed by receive packet bus 115. In this example, 5 the first transmission rate is the 2.048 Mb/sec 32 time slot format rate and the internal receive packet bus 115 rate is 8.192 Mb/sec. Receive process modules 113 also pre-process the received packets. For example, the pre-processing includes adding an internal receive 10 destination code field, processing time stamp information, monitoring for transmission errors and dropping any packets which have incurred such errors in their headers. Bus controller 114 interacts with each of receive process modules 113-1 through 113-Y and 15 receive packet bus 115 to control the flow of packets onto receive packet bus 115. Receive access modules 116-1 through 116-X each monitors activity on receive packet bus 115 to detect packets assigned to it via the receive destination code in the packet header. 20 Receive access modules 116-1 through 116-X reconstruct a facsimile of the original signals applied to transmit access modules 106-1 through 106-N from one or more remote access interface transmitters 101. Outputs from each of receive access modules 116-1 through 116-X are 25 32 time slot time division multiplexed signals which are supplied to digital line interface units 117-1 through 117-X. Each of digital line interface units 117-1 through 117-X converts a unipolar 32 time slot time division multiplexed signal having a rate of 30 2.048 Mb/sec into a standard DSI PCM format having a rate of 1.544 Mb/sec for transmission as desired over associated digital transmission lines 118-1 through 118-X, respectively. It is noted that the number Y of receive process modules 113 may be more or less than the 35 number X of receive access modules 116.

For simplicity and clarity of description, the following description of the modules of the transmitter 101 and receiver 102 is on a per time slot basis. It will be apparent to those skilled in the art that the modules are time-shared to process the 32 time slots of the internal signals.

Transmit Access Module

FIG. 2 shows in simplified block diagram form details of transmit access modules 106. Each of transmit access modules 106 includes a voice processing module 201 and a packet assembler 202. Voice processing module 201 includes echo canceler 203, encoder 204, speech detector 205 and signal classifier 206. Voice processing module 201 is employed to encode voiceband signals on a time slot by time slot basis including speech and voiceband data into an ADPCM encoded output signal which is supplied to packet assembler 202. During time slots which are assigned to digital data signals, voice processing module 201 becomes transparent and those signals are supplied directly to packet assembler 202 without any voice signal processing in a well known manner (not shown). In processing the voice band signals, echo canceler 203 is supplied with the 32 time slot transmit PCM signal from an associated one of digital line interfaces 105 (FIG. 1) and with a receive PCM signal from co-located access interface receiver 121 (FIG. 1) to cancel echos in well-known fashion. The receive PCM signal is specifically obtained from an associated one of receive access modules in the co-located access interface receiver 121. Such echo canceler units are well known in the art. See, for example, U.S. patent 3,500,000, and an article entitled "A Single-Chip VLSI Echo Canceler", by D. L. Duttweiler et al, BSTJ, Vol. 59, No. 2, February 1980, pages 149-160.

Speech detector 205 is supplied with the output from echo canceler 203 and the receive PCM signal from the associated access interface receiver 121

(FIG. 1). Speech detector 205 detects the presence of voiceband energy in each time slot of the 32 time slots of the transmit PCM signals supplied to it. Speech detector 205 generates an active-inactive output for each of the time slots of the transmit PCM signal which is supplied to controller 207 and a noise estimate value which is supplied to header generator 208 in packet assembler 202. Such speech detector arrangements are known in the art. See, for example, U.S. patent 4,277,645, issued to C. J. May, Jr., on July 7, 1981.

Signal classifier 206 is also supplied with the output signal from echo canceler 203 and the receive PCM signal from the associated access interface receiver and classifies the signals in the transmit PCM time slots as being voice or nonvoice signals. The voice-nonvoice output indication from signal classifier 206 is supplied on a per time slot basis to controller 207 in packet assembler 202. Such signal classifier arrangements are also well known in the art. See, for example, U.S. patent 4,281,218, issued to Chin-Sheng Chuang et al on July 28, 1981.

Encoder 204 is a variable rate encoder for converting the transmit PCM signals into ADPCM output signals. Controller 207 supplies a packet active control signal, and an encoding rate and type of coding control signal to encoder 204. The encoding rate may be one of a plurality of rates selected as desired depending on the network configuration for the particular time slot in the PCM signal and upon the signal classifier output. The packet active control signal is useful to facilitate for handling late-arriving packets and for recovering from packet loss and transmission errors in an associated remote access

0234860

interface receiver in accordance with an aspect of the invention. In encoder 204 the packet active signal is employed to control initialization, adaptation and holding of its state variables. Details of encoder 204 are shown in FIG. 25 and described below in conjunction with the state diagram of FIG. 26.

The ADPCM output from encoder 204 is supplied to formatter 209 in packet assembler 202. Formatter 209 includes, in this example, a RAM memory unit and a plurality of counters (not shown) which perform a shift register function for the purpose of rearranging the supplied bits into a packet information field format as shown in FIGs. 3 and 4 for the  $\mu$ -law PCM signal format and for the 32 kilobit/sec ADPCM signal format, respectively. It should be noted that FIGs. 3 and 4 depict the formats for an individual time slot, for example, time slot zero, and are repeated for the remaining time slots 1 through 31 in each frame of the PCM transmit signals. Specifically, formatter 209 performs the function of grouping in a prescribed manner the individual bits of each time slot into the packet information field for that time slot, in accordance with an aspect of the invention. The grouping of the bits is such as to facilitate processing of the packet information field, in accordance with an aspect of the invention. It is noted that the grouping of the bits is readily realized by an addressing scheme of the RAM memory unit memory locations. For example, the bits of the  $\mu$ -law PCM or the ADPCM samples can be written into the RAM memory locations in parallel for a predetermined number of repetitive frames and then the "groups" of bits are formed from the predetermined number of frames by reading them out in series beginning with the group of most significant bits to the group including the least significant bits of the samples from the predetermined number of frames. Thus, as shown in FIG. 3, for  $\mu$ -law PCM signals there are eight bits per

time slot and 128 frames are included in a packet interval. In this example, a packet interval is 16 milliseconds. Then, the sign(s) bits for a particular time slot from the 128 frames are grouped together in 128 bit positions in the RAM memory of  
5 formatter 209. The (a) bits from the 128 frames for the particular time slot are grouped together, also in 128 bit positions of the RAM memory, and so on through the (z) bits. The groups of bits from the 128 frames  
10 for the time slot form the packet information field which is outputted to multiplexer 210.

For the 32 kbit/sec ADPCM format, the time slot includes four bits, namely, s, 1, 2 and 3, and four so-called don't care bits denoted by the character x.  
15 Thus, the 128 sign bits are grouped together in bit positions of the RAM memory in formatter 209. The 128 (1)-bits are also grouped together in bit positions of the RAM memory as are the 128 (2)-bits and 128 (3)-bits. As indicated in FIG. 4, the (3)-bits are considered  
20 enhancement bits level 1, and the (2)-bits are the enhancement bits level 2. These level 1 and level 2 enhancement bits are the groups of bits which are controllably droppable, that is, they can be removed from voice packets as desired, in accordance with an  
25 aspect of the invention, as will be explained later. In addition to the 4-bit ADPCM sample, the system configuration may call for a 3-bit ADPCM sample transmission or a 2-bit ADPCM sample transmission in a particular time slot. For 3-bit ADPCM, only the s, 1  
30 and 2 bits are used and for 2-bit ADPCM, only the s and 1 bits are used. It is noted that this packet information field is formed for each of the 32 time slots in the incoming signal. That is to say, a packet information field is formed for each of the time slots  
35 and, hence, for each of the channels being transmitted. The writing-in of data to and the reading-out of the packet information fields from formatter 209 is

controlled by controller 207 as explained below. The packet information field output from formatter 209 is supplied to multiplexer 210 where it is combined with an appropriate packet header from header generator 208.

5 Header generator 208 is operative to generate the packet header as shown in FIG. 5 on a per-packet basis under control of controller 207. Header generator 208 includes memory for storing the desired header fields. The packet header fields include an  
10 internal field which has an internal destination code that identifies the one of transmit process modules 109 (FIG. 1) that will process the packet for transmission to a remote access interface receiver. The internal destination module code is discarded in the transmit  
15 process module prior to transmission. Another field is the logical channel number (LCN) which identifies where in the transmission system the packet is to be transmitted. The time stamp field includes the local time at which the packet was originated, namely, the  
20 packet originate time (POT), and is obtained from a local time signal from local timing unit 119 (FIG. 1). In this example, the local time rate is 1 kHz. The BDI field includes information that is used to select the type of processing for the packet and is used to  
25 indicate the type of packet that has been generated. It is again noted that for digital data and voice band data none of the bits are droppable. In the access interface transmitter 101, the BDI for the particular time slot is obtained from the particular system configuration stored  
30 in controller 207. The BDI field includes two subfields, one contains the type of coding which is being used for the particular packet (receive status) and the other contains information concerning previous processing of the packet, e.g., whether any of the  
35 enhancement fields have been dropped (packet length value). The sequence number (SEQ.No.) field includes the initial packet identifier, if the packet happens to

be the first packet occurring after a period of silence or the packet virtual sequence number if it is a subsequent one of consecutive packets. The use of the virtual sequence number scheme is described below. The  
5 noise estimate field includes the background noise estimate value generated by speech detector 205. A check sequence is calculated over the entire packet header for insertion into a header check sequence field. These header field signals are loaded into the header  
10 generator 208 under control of controller 207. The header is supplied to multiplexer 210 where it is combined with the packet information field and, subsequently, written into packet buffer 211. The writing into packet buffer 211 is also under control of  
15 controller 207 in conjunction with write circuit 212. The packets in packet buffer 211 are read out to transmit packet bus 108 (FIG. 1) under control of read circuit 213 and bus controller 107 (FIG. 1). Read circuit 213 sends a packet ready signal to bus  
20 controller 107 and when bus controller 107 transmits a send packet signal, read circuit 213 causes the packet to be read from packet buffer 211 to transmit packet bus 108. Operation of bus controller 107 is described below.

25           Controller 207 controls the operation of encoder 204 and packet assembler 202. To this end, controller 207 includes control logic and a plurality of packet interval timers, one for each time slot (not shown) for effecting a sequence of control steps in  
30 generating a packet in assembler 202 and for controlling the encoder 204. Again, in this example, the packet interval is 16 milliseconds.

FIG. 6 is a flow chart showing a sequence of steps which are effected in controller 207 in  
35 controlling the configuration and operation of encoder 204 (FIG. 2). Accordingly, the sequence is entered for each time slot of a recurring frame via 601.

Thereafter, conditional branch point 602 tests to determine whether a packet is active according to the output from speech detector 205. If the test result in step 602 is NO, conditional branch point 603 tests to

5 determine if the present time slot is active. The activity is sensed by interrogating the state of the output from speech detector 205. If the test result in step 603 is NO, operational block 604 causes controller 207 to output a packet inactive (false)

10 signal which is supplied to encoder 204 (FIG. 2) and the encoder control sequence is exited via 605. That is to say, encoder 204 is disabled during time slot intervals that both the packet and time slot are determined to be inactive. If the test result in step 603 is YES, the

15 time slot is active and operational block 606 causes a packet interval timer (not shown) in controller 207 to start counting the packet interval. This indicates the beginning of a packet since the packet indication in step 602 was inactive and now the time slot as indicated

20 in step 603 is active. Consequently, this is the first time slot in a packet. Thereafter, control is transferred to operational block 607 which causes controller 207 to output a packet active (true) signal. The packet active signal is supplied from controller 207

25 to enable encoder 204 (FIG. 2). Returning to step 602, if the test result is YES, the packet remains active and operational block 607 causes the packet active signal to be supplied from controller 207 to encoder 204. Operational block 608 causes the stored system

30 configuration, i.e., the type of coding, for the present time slot to be accessed. Conditional branch point 609 tests the system configuration for the present time slot to determine if the encoding is so-called embedded coding. The embedded coding scheme is known in the art.

35 See, for example, U.S. patent 3,781,685 issued December 25, 1973, and an article by David J. Goodman entitled "Embedded DPCM for Variable Bit Rate

Transmission", IEEE Transactions On Communications, Vol. Com-28, No. 7, July 1980, pages 1040-1046. If the test result in step 609 is NO, the type of coding is not embedded and operational block 610 causes the encoding stored in the system configuration in controller 207 to be employed, i.e., for example, bypass encoder 204 if digital data is being transmitted, 4-bit ADPCM, 3-bit ADPCM or 2-bit ADPCM coding. Thereafter, the sequence is exited via 605. If the test result in step 609 is YES, the coding is embedded and conditional branch point 611 tests to determine whether the transmission activity is nonvoice. If the test result in step 611 is NO, i.e., the activity is voice, and operational block 610 causes the stored encoder configuration to be used and the sequence is thereafter exited via 605. If the test result in step 611 is YES, the activity is nonvoice, i.e., for example, voiceband data, and operating block 612 causes a premium transmission quality to be provided to this channel, i.e., time slot. In this example, 4-bit ADPCM encoding to be used. Thereafter, the sequence is exited via 605. The stored encoder configurations are, for example, 4-bit, 3-bit or 2-bit embedded coding ADPCM, and 4-bit, 3-bit or 2-bit non-embedded coding ADPCM. In for example a 4/2-bit embedded coding arrangement two of the four bits are so-called core bits and cannot be dropped, only the two least significant bits can be dropped. Similarly, in a 4/3 embedded coding arrangement, three of the bits are core bits and only the least significant bit can be dropped.

FIG. 7 is a flow chart of a sequence of operations effected by controller 207 in controlling packet assembler 202 (FIG. 2) to generate a packet which is to be supplied to transmit packet bus 108 (FIG. 1) in access interface transmitter 101. Accordingly, the sequence is entered for each time slot of a recurring frame via 701. Thereafter, conditional branch point 702

tests to determine whether the packet is active. If the test result of step 702 is NO, conditional branch point 703 tests to determine whether the time slot is active. If the test result in step 703 is NO, the sequence is exited via 704. That is to say, there is no packet to be presently generated for this particular time slot. If the test result of step 703 is YES, operational block 705 causes a packet sequence number counter to be incremented. This is done because step 702 yielding a NO test result and step 703 yielding a YES test result indicate the start of a new packet. It should be noted that the sequence number counter, in this example, is a modulo 15 counter, i.e., it counts 1-15 continuously. There is no zero state. The zero (0) state is used instead of a flag for identifying the initial packet in a spurt of contiguous packets. A particular packet sequence may be, for example, 0, 5, 6, 7, 8, ..., 15, 1, 2, 3, 4, 5, .... Another sequence may be 0, 14, 15, 1, 2, ..., 12, 13, 14, 15, 1, .... Such sequences are known as virtual sequences. The zero is inserted to indicate the initial or scheduled packet in a speech or information spurt. It is noted that the number in the virtual sequence is incremented for each packet in the information spurt including the first packet. Thus, the unique number identifying the initial packet in the information spurt replaces a number in the virtual sequence, as shown above. The virtual sequence numbering of the packets in an information spurt simplifies, in accordance with an aspect of the invention, the reconstruction of the digital signals in an associated remote access interface receiver 102. Conditional branch point 706 tests to determine whether this particular time slot was active in the last previous frame. If the test result in step 706 is NO, operational block 707 causes a zero (0) to be stored in the header generator 208 (FIG. 2) sequence number store. This indicates the start of a new sequence of packets in

the information spurt. Thereafter, operational block 708 causes the packet interval timer to begin timing the packet interval. It should be noted that this packet interval timer is synchronous with the

5 packet interval timer of step 606 of FIG. 6. Returning to step 706, if the test result is YES, the packet is another in the current information spurt and operational block 709 causes the current sequence number counter value to be stored in the sequence number store in

10 header generator 208 (FIG. 2). Thereafter, operational block 708 causes the packet interval timer to start timing the packet interval. Then, operational block 710 causes the output sample from encoder 204 (FIG. 2) for the current time slot to be written into formatter 209.

15 Returning to step 702, if the test result is YES, the current packet is still active and operational block 710 causes the output sample from encoder 204 (FIG. 2) for the current time slot to be written into formatter 209 (FIG. 2).

20 Conditional branch point 711 tests to determine if the current packet interval is complete. Again, in this example, the packet interval is 16 milliseconds. If the test result of step 711 is NO, the packet information field is not yet completed and

25 the sequence is exited via 704. If the test result in step 711 is YES, the packet is complete and ready to be assembled. Operational block 712 causes the multiplexer 210 (FIG. 2) to be set for the header output from header generator 208 (FIG. 2). Operational

30 block 713 causes the header information to be loaded into the stores in header generator 208. That is to say, the internal destination field, the noise estimate, the BDI, the sequence number (SEQ.No.), the logical channel number (LCN) and the time stamp (TS) fields are

35 loaded into the header stores in header generator 208 (FIG. 2). The packet originate time (POT) is inserted into the TS field. It is noted that  $POT = LTA - TS$ .

That is, the POT is the packet arrival time LTA, i.e., the local time at which the packet arrives at a node, less the TS value in the time stamp field of the arriving packet. If the packet is being originated at this node, i.e., access interface transmitter, then TS = 0. It is important to note that the same local time signal is used in all modules in a node. This use of the same local time signal in conjunction with using the packet arrival time LTA at and packet departure time LTD from a node to compute the time stamp value simplifies the time stamp computation and allows use of only one time stamp field in the packet header, in accordance with an aspect of the invention. Operational block 714 causes the header fields (FIG. 5) to be written via multiplexer 210 into packet buffer 211 (FIG. 2). Operational block 715 causes multiplexer 210 to be set for the formatter 209 output. This output is the packet information field which follows the packet header. Operational block 716 causes the packet information field from formatter 209 to be written via multiplexer 210 into packet buffer 211. Consequently, the completed packet is now stored in packet buffer 211. Thereafter, the sequence is exited via 704.

#### Bus Controller

FIG. 8 shows in simplified block diagram form details of bus controller 107 of FIG. 1. It is noted that bus controller 107 employed in access interface transmitter 101 interfaces with each of transmit access modules 106-1 through 106-N and transmit packet bus 108. Bus controller 114 employed in access interface receiver 102 is essentially identical to bus controller 107. Bus controller 114 differs from bus controller 107 in that it is employed in access interface receiver 102 to interface with each of receive process modules 113-1 through 113-Y and receive packet bus 115. Accordingly, only bus controller 107 will be described in detail, since the operation of bus controller 114 will be

apparent therefrom to those skilled in the art. The bus controller 107 includes input controller 801, service request FIFO 802, i.e., a first in-first out type of buffer storage unit, output controller 803 and bus activity sensor 804. Input controller 801 includes combinational logic for the polling of the packet ready requests from the transmit access modules 106-1 to 106-N and the conversion of these requests into the transmit access module address for storage in the service request FIFO 802.

FIG. 9 shows a detailed state diagram of the operation of input controller 801 (FIG. 8). The state diagram consists of two states, an IDLE state and a REQUEST SERVICE state, in which a service request is stored in service request FIFO 802. At system reset, the system enters the IDLE state and remains in the IDLE state until there is a packet ready request signal from one of transmit access modules 106 (FIG. 2). When the packet ready request signal is received from any of transmit access modules 106, control passes to the REQUEST SERVICE state, and the packet ready service request is stored in service request FIFO 802. When there is no longer a packet ready service request signal, input controller 801 returns to the IDLE state. However, if there is another packet waiting, indicated by a packet ready service request, bus controller 107 passes back into the REQUEST SERVICE state and stores the packet ready service request in service request FIFO 802.

Bus activity sensor 804 examines packet activity on transmit packet bus 108 primarily through what is called the packet window bus and determines whether transmit packet bus 108 is free to support another packet being outputted from one of transmit access modules 106. Bus activity sensor 804 controls the operation of output controller 803 in conjunction with the empty (E) signal supplied by service request

FIFO 802. That is, when there is no activity on transmit packet bus 108, output controller 803 is enabled to release another send packet message to one of transmit access modules 106, if indeed there is a  
5 request queued in service request FIFO 802. When there is activity on transmit packet bus 108, output controller 803 is disabled until that activity ceases. Output controller 803 contains combinational and sequential logic (not shown) for first accessing service  
10 request FIFO 802 and converting the transmit access module number which was stored there into the correct send packet signal which will be transmitted to one of the transmit access modules 106.

FIG. 10 shows a detailed state diagram  
15 illustrating the operation of output controller 803 of bus controller 107. Upon system reset, output controller 803 goes into an IDLE state and it remains in the IDLE state as long as service request FIFO 802 remains empty. When a service request is stored in  
20 service request FIFO 802, control passes to the SEND PACKET state. In the SEND PACKET state, output controller 803 reads the service request from FIFO 802 and formats the correct send packet signal for transmission to the appropriate one of transmit access  
25 modules 106. At this time, output controller 803 starts an interval counter called "C" which measures the packet activity interval of transmit packet bus 108. As long as the measured interval of counter C is less than some predetermined time interval T1, controller 803 waits for  
30 the corresponding packet to appear on transmit packet bus 108. If no packet appears when the counter time interval C is equal to T1, output controller 803 passes to the TURN-OFF state and the send packet signal is relinquished to the particular one of transmit access  
35 modules 106. Once the send packet signal is relinquished, output controller 803 returns to the IDLE state and waits for another service request to be stored

in FIFO 802. Thereafter, the new packet ready service request is processed as described above. If, however, transmit packet bus 108 becomes active, output controller 803 passes from the SEND PACKET state to the  
 5 PACKET IN PROGRESS (PIP) state. As long as a packet is on transmit packet bus 108, output controller 803 remains in the PIP state. In the PIP state, output controller 803 continues to monitor the counter C count to determine if it is less than some other larger  
 10 predetermined interval, T2. If for some reason the count in counter C becomes equal to interval T2, the output controller 803 passes to the TURN-OFF state and relinquishes the send packet signal to the particular one of transmit access modules 106. If the counter C  
 15 never reaches a count equal to interval T2, but the end of a packet is detected, as evidenced by transmit packet bus 108 becoming idle once again, output controller 803 will return to the IDLE state, waiting for the next service request, i.e., packet ready signal, to be  
 20 received from one of transmit access modules 106. As part of the end of packet transition from the PACKET IN PROGRESS state to the IDLE state, the send packet signal is relinquished to the particular one of transmit access modules 106 being serviced.

25 Transmit Process Module

FIG. 11 shows in simplified block diagram form details of transmit process modules 109 employed in access interface transmitter 101 of FIG. 1. Each transmit process module 109 monitors transmit packet  
 30 bus 108 for packets, checking the destination addresses as they appear on transmit packet bus 108. When a particular one of transmit process modules 109 detects its own address in the destination field of a packet header, the packet is supplied to delay 1101.  
 35 Delay 1101 allows input controller 1102 to process the packet as it is received. To this end, the packet is also supplied to input controller 1102, which controls

the entire packet input process of transmit process module 109. That is, input controller 1102 monitors transmit packet bus 108 and applies appropriate controls to multiplexer 1103, buffer 1104 and up/down counter 1105. Buffer 1104 is a so-called FIFO type, i.e., first in-first out type of buffer storage unit. Buffer 1104 is linked also with an up/down counter 1105 which counts the number of bytes of packet data stored in buffer 1104. Output controller 1106 controls reading packets out of transmit process module 109. To this end, output controller 1106 controls the read cycle from buffer 1104, multiplexer 1107, line formatter 1108 and down-counting of up/down counter 1105. Off line from the packet data flow path, time stamp calculator 1109 performs the packet originate time (POT) to time stamp (TS) conversion. Up/down counter 1105 supplies its count, i.e., the number of bytes of packet data stored in buffer 1104, to a first input of each of comparators 1110, 1111 and 1112. Comparators 1110-1112 compare the amount of packet data stored in buffer 1104 with a set of three fixed predetermined thresholds, namely, thresholds TL1, TL2 and TL3. The comparisons of the amount of packet data stored in buffer 1104 to these thresholds determine whether or not packets being processed in transmit process module 109 will, if permissible, have one or more of the enhancement bit fields removed, in accordance with an aspect of the invention, on being inputted into buffer 1104. Comparators 1110, 1111 and 1112 generate buffer status signals BS1, BS2 and BS3, respectively. Buffer status signals BS1, BS2 or BS3 are generated when the count in counter 1105 is greater than the corresponding one of thresholds TL1, TL2 or TL3, respectively. Buffer status signals BS1, BS2 and BS3 are supplied to input controller 1102 in order to determine whether input packets should have the bits in one or more of the enhancement bit fields dropped. The algorithm for

dropping bits is as follows: if the amount of packet data stored in buffer 1104, as measured by up/down counter 1105, is greater than the first predetermined fixed threshold TL1, the BS1 output from comparator 1110 is true, i.e., a logical 1, and the level 1 enhancement bit field will be dropped from the current packet being processed; thus shortening the packet size and slowing down the speed at which buffer 1104 fills with packet data, in accordance with an aspect of the invention. If the level 1 enhancement bit field has already been dropped or the packet type does not permit bit dropping, then no further action will be taken. If buffer 1104 continues to fill beyond the second predetermined fixed threshold TL2, comparator 1111 yields a true BS2 signal and both the level 1 and level 2 enhancement bit fields will be dropped from the current packet being processed. This will further shorten the size of the packets and further slow the rate at which buffer 1104 fills with packet data, in accordance with an aspect of the invention. Again if both the level 1 and level 2 enhancement bit fields have already been dropped or the packet is of a type that does not permit bit dropping, then no further action will be taken. If only the level 1 enhancement bit field had been dropped the level 2 enhancement bit field would be dropped. It is noted that there is some maximum amount of data which the buffer 1104 can store. This maximum amount of data stored is indicated by the third predetermined fixed threshold TL3. Therefore, if the amount of data stored in buffer 1104 exceeds threshold T3, the current packet being processed is discarded in its entirety and no further packet data will be allowed into the buffer 1104 until some of the packets stored therein have been outputted. This prevents overflow of buffer 1104 and prevents a fraction of a packet from being inputted into buffer 1104. Only whole packets should be stored in buffer 1104. A fractional packet is defined as an

arbitrary piece of the received input packet, possibly only a header.

Delay 1101 accepts packet data as its input as seen from the packet data bus 108. Its output is the same packet data delayed by a predetermined number of clock pulses. The data output from delay 1101 is applied to multiplexer 1103. Multiplexer 1103 is employed to insert a new bit-dropping indicator field (BDI) generated in input controller 1102 at the appropriate time in the header of the packet being processed. The new BDI field will indicate whether none, one or both of the enhancement bit fields have been dropped from the packet being processed. Multiplexer 1103 is controlled by input controller 1102 in order to insert the bit-dropping indicator field into the packet's header at the appropriate time. Multiplexer 1103 output is supplied to buffer 1104. Input controller 1102 also supplies an end of packet (EOP) signal to buffer EOP. This EOP signal is supplied into a separate storage element of the buffer 1104 associated with each byte of the packet data being processed in parallel. Normally, the EOP signal is a logical 0, i.e., a false signal. When the packet has reached its end, the EOP signal associated with the final byte of packet data is set to a logical 1, i.e., a true signal. The write signal is used to control buffer 1104 in order to drop the level 1, level 2 or both of the enhancement bit fields as desired, under control of input controller 1102. The write signal causes the data appearing at the output of multiplexer 1103, as well as the EOP signal, to be stored in buffer 1104 in parallel. When buffer 1104 is empty, it generates an empty (E) indication signal which is supplied to up/down counter 1105 and to output controller 1106. This empty (E) indication signal causes up/down counter 1105 to be reset to its initial condition. By this method, up/down counter 1105 is

synchronized to the amount of packet data stored in buffer 1104. A further input to buffer 1104 is a read (R) signal. The read (R) signal supplied by output controller 1106 enables buffer 1104 read circuitry to output the next byte of packet data including the EOP signal. The packet data from the buffer 1104 is applied to multiplexer 1107 as well as to time stamp calculator 1109. The EOP signal is supplied to output controller 1106.

Time stamp calculator 1109 calculates the final value of the time stamp (TS) for each packet as it leaves access interface transmitter 101. This is accomplished by latching the packet originate time (POT) field of the packet and subtracting that packet originate time (POT) from the current local time (LT) indication. That is, we are calculating the packet departure time (LTD) minus the packet originate time (POT), namely,  $TS' = LTD - POT$ . This updated  $TS'$  result is supplied to multiplexer 1107 for insertion into the packet header time stamp field as the new TS value at the appropriate instant under control of output controller 1106. The use of the packet departure time LTD in conjunction with the POT which was determined by using the packet arrival time LTA at the node simplifies the current time stamp calculation and allows use of only one time stamp field in the packet header, in accordance with an aspect of the invention. Again, it is noted that the same local time signal is used for the time stamp calculations in the node and that the same single time stamp field is used to transport both the packet originate time (POT) value and the updated time stamp (TS) value. The packet data output of multiplexer 1107 is supplied to line formatter 1108. Line formatter 1108 is also supplied with a data available (DA) signal from output controller 1106. The DA signal provides an indication of when packet data has been applied to the digital line formatter 1108 via

5 multiplexer 1107. Such line formatter arrangements are known in the art. They typically perform such functions as idle flag insertion into the data stream during times when there are no packets, as well as zero bit stuffing to assure that the data patterns do not appear as a flag on the transmission line. Furthermore, line  
10 formatter 1108 provides a calculation of a so-called header check sequence of the packet to aid in detecting any transmission errors.

10 Output controller 1106 controls outputting of packet data from transmit process module 109. Inputs to output controller 1106 include the empty (E) indication signal and the end-of-packet (EOP) indication signal from buffer 1104. Output controller 1106 operates  
15 multiplexer 1107 as well as line formatter 1108 in order to enable the line formatter 1108 to process active packet data.

Up/down counter 1105 is employed to measure the amount of the data stored in buffer 1104. The  
20 amount of data stored in buffer 1104 is indicated by causing counter 1105 to count up when data is being written into buffer 1104 and to count down when data is being read out. To this end, buffer 1104 write control signal is supplied from input controller 1102 to the  
25 upcount input (U) of up/down counter 1105 and buffer 1104 read control signal from output controller 1106 is supplied to the downcount (D) input of counter 1105. Up/down counter 1105 is reset when buffer 1104 is empty via signal E.

30 Operation of input controller 1102 is shown in the state diagram of FIG. 12. From system reset, the IDLE state is entered. Input controller 1102 remains in the IDLE state as long as no packets appear on transmit packet bus 108 and to count the amount of packet data  
35 stored in buffer 1104. When a packet is indicated on transmit packet bus 108, input controller 1102 passes to the QUERY state. In the QUERY state, input controller

1102 determines if the internal destination code in the packet header matches the address of this of this particular process module 109. If the packet internal destination code field does not match the particular process module 109 address, input controller 1102 returns to the IDLE state until another packet appears on transmit packet bus 108. If, however, the internal destination code does match the particular process module 109 address, input controller 1102 passes into the LATCH state. In the LATCH state, input controller 1102 latches the buffer status indications BS1, BS2 and BS3 for use in processing the current packet. Input controller 1102 also sets a counter C to a large nonzero value so that counter indications will not affect the next few data bytes of the packet being processed. Upon completion of these functions, input controller 1102 passes from the LATCH state to the COLLECT DATA state. In the COLLECT DATA state, input controller 1102 decrements the counter C for each byte of data which appears on transmit packet bus 108. Additionally, input controller 1102 supplies write pulses to buffer 1104 and up/down counter 1105 in order to store the packet data as it appears on transmit packet bus 108 and to count the amount of packet data stored in buffer 1104. When the bit-dropping indicator (BDI) field is available on packet transmit bus 108, input controller 1102 passes from the COLLECT DATA state to the PROCESS BDI state. In this PROCESS BDI state, input controller 1102 performs several functions. First, input controller 1102 latches the BDI field of the packet as it is entering the process module 109. Based on the old BDI and the buffer status indications BS1, BS2 and BS3, input controller 1102 chooses an appropriate counter value, C, consistent with the amount of data stored in buffer 1104. This counter value is used to determine the length of the packet being supplied to buffer 1104. Finally, in the PROCESS BDI state, input controller 1102

0234860

operates multiplexer 1103 to reinsert and store a new bit-dropping indicator (BDI) field derived from the old bit-dropping indicator and the buffer status indications as described below. When the BDI field is no longer available, input controller 1102 passes back to the COLLECT DATA state in order to collect the remainder of the packet, continuously decrementing the counter C. When the counter C goes to 0, or the end of a packet appears on transmit packet bus 108, input controller 1102 passes to the DISABLE state. In the DISABLE state, input controller 1102 first generates the end-of-packet (EOP) indication which will be stored in buffer 1104. Input controller 1102 also disables any further writing of data into buffer 1104 and upcounting of counter 1105. When these functions are accomplished, input controller 1102 passes to the IDLE state awaiting the next packet on transmit packet bus 108.

FIG. 13 depicts a flow chart of the sequence of steps in input controller 1102 in setting an internal counter to determine bit dropping, packet length and the current BDI field for the packet being processed. Although the steps are shown sequentially in the flow chart, it will be apparent to those skilled in the art that the preferred implementation of these functions is with a read only memory (ROM) which examines all the necessary inputs simultaneously and performs all of the steps substantially simultaneously to yield the BDI field output and to set the internal counter in input controller 1102. The flow chart shown in Fig. 13 is entered for every packet which appears on packet transmit bus 108 in order to determine correct internal counter values. On appearances of a packet having an internal destination code which matches the address for this transmit process module 109, the sequence is entered via 1301. The first task to be performed is indicated in operational block 1302 at which time the buffer status values BS1, BS2 and BS3 are latched. This

occurs simultaneously with the LATCH state as described in the previous state diagram of FIG. 12. Thereafter, conditional branch point 1303 tests to determine whether or not buffer 1104 is full. That is, whether additional data may be stored therein. If buffer 1104 is indeed full, as indicated by BS3 being true, i.e., a logical 1, further operation to determine the countervalue is abandoned and the process returns through the disable block 1304 and return 1305 to its initial state of waiting for a packet to appear on transmit packet bus 108 destined for this transmit process module 109. That is to say, the current packet being processed is dropped in its entirety by disabling writing of buffer 1104 (FIG. 11). If, however, there is room in the buffer 1104 for an additional packet or more, as indicated by the test in step 1303 yielding a NO result, the incoming BDI is latched, as indicated in block 1306, by input controller 1102. Conditional branch point 1307 tests the BDI field to determine whether the BDI field indicates a packet which can have one or more of the enhancement bit fields dropped or not. If the BDI field indicates that none of the enhancement bit fields can be dropped and the test result is NO, control is transferred to block 1308 and the internal counter is set to be the maximum value allowed for a packet in the system. Control is then returned to the main process via 1305. If the test result in step 1307 is YES, conditional branch point 1309 tests to determine whether BS1 is true, i.e., a logical 1. BS1 is an indication of whether or not the amount of data stored in buffer 1104 is greater than the first predetermined threshold TL1. If the amount of data stored in buffer 1104 is not greater than the threshold TL1, as indicated by BS1 being false, i.e., a logical 0, none of the enhancement bit fields need be dropped and control is transferred to operational block 1310. Operational block 1310 causes the counter value to be set consistent with the incoming

BDI. The outgoing BDI is also set equal to the incoming BDI. It should be noted that the incoming BDI may indicate that one or both of the enhancement bit fields have been dropped or that none of the enhancement bit fields has been dropped. This dropping of one or more of the enhancement bit fields may have occurred in some other switching or transmission node in the packet system. Thereafter, control is returned via 1305. If, however, the test result in step 1309 is YES, the amount of data stored in buffer 1104 is greater than the first threshold TL1 and conditional branch point 1311 tests BS2 to determine whether or not the amount of data stored of buffer 1104 is greater than some predetermined threshold TL2. If the test result in step 1311 is NO, i.e., BS2 is not greater than threshold TL2, then conditional branch point 1312 tests to determine whether the level 1 enhancement bit field has been dropped. This test is performed by examining the BDI field in the incoming packet header. If the test result in step 1312 is YES, the level enhancement bit field has been dropped, and control is transferred to operational block 1310 where the internal counter value is set consistent with the incoming BDI and the outgoing BDI is set to equal the incoming BDI. If the test result in step 1312 is NO, the level enhancement bit field has not been dropped, and control is transferred to operational block 1313 where the internal counter is set in order to drop the level 1 enhancement bit field. Operational block 1314 sets the outgoing BDI to indicate that the level 1 enhancement bit field has indeed been dropped. Thereafter, control is returned to the main process via 1305. Returning to step 1311, if the test result therein is YES, the amount of data stored in buffer 1104 is greater than threshold TL2, and conditional branch point 1315 tests the BDI field of the packet being processed to determine whether the level 1 enhancement bit field has been dropped. If the test result in step

1315 is YES, the level enhancement bit field has been dropped, and operational block 1316 causes the internal counter to be set to drop the level 2 enhancement bit field. Thereafter, operational block 1317 causes the outgoing BDI to be set to indicate that both the level 1 and level 2 enhancement bit fields have been dropped. Once BDI has been set, control is returned to the main process via 1305. If the test result in step 1315 is NO, the level 1 enhancement bit field has not been dropped, and operational block 1318 causes the internal counter to be set to drop both the level 1 and level 2 enhancement bit fields. Thereafter, control is transferred to operational block 1317 which sets the outgoing BDI to indicate that both level 1 and level 2 enhancement bit fields have been dropped. Thereafter, control is returned to the main process via 1305. Although only two enhancement bit fields are used in this example, it will be apparent that this process could be expanded for any number of enhancement bit fields. It should also be noted that the bit fields are dropped from the packet in a prescribed order beginning from the bit field including at least significant bits toward the bit field including the most significant bits. It should be noted that the enhancement bit fields are dropped in order from the enhancement bit field including the last significant bits of the corresponding transmission channel toward the enhancement bit field including the most significant bits of the corresponding transmission channel.

FIG. 14 depicts a state diagram of a sequence of steps illustrating the operation of output controller 1106 in the transmit process module 109 of FIG. 11. The state diagram is entered from system reset and the output controller 1106 transfers to the IDLE state.

Output controller 1106 remains in the IDLE state as long as buffer 1104 is empty. When buffer 1104 is not empty, as indicated by a logical 0 empty (E) signal from buffer

1104, output controller 1106 transfers to the OUTPUT  
PACKET state, output controller 1106 enables reading of  
a packet from buffer 1104 as well as decrementing  
up/down counter 1105. Output controller 1106 also  
5 operates multiplexer 1107 to allow passage of the packet  
data from buffer 1104. Finally, as each byte of packet  
data is read from buffer 1104, output controller 1106  
enables line formatter 1108 to perform its operation.  
When the time stamp (TS) field is available in the  
10 packet being read from buffer 1104, output controller  
1106 passes to the TS state. In the TS state, output  
controller 1106 operates multiplexer 1107 to insert the  
new time stamp field from time stamp calculator 1109 in  
the packet header. As with other bytes of packet data  
15 being outputted, output controller 1106 also enables  
line formatter 1108 to code the time stamp field for  
transmission to the digital line interfaces. When the  
time stamp field is no longer available, control passes  
back to the OUTPUT PACKET state and the above-mentioned  
20 functions are iterated. Output controller 1106 remains  
in the OUTPUT PACKET state as long as buffer 1104 is not  
empty and it is not the end of a packet as indicated by  
the EOP signal. The end of a packet is indicated by a  
logical 1 EOP signal appearing in the last byte of  
25 packet data from buffer 1104. The logical 1 EOP signal  
causes control to pass to the DISABLE state. In the  
DISABLE state, output controller 1106 disables the  
decrementing of up/down counter 1105, disables any  
further reading of buffer 1104 and causes the DA signal  
30 to become a logical 0 indicating to line formatter 1108  
that the packet is no longer available. When line  
formatter 1108 no longer has packet data available to be  
outputted, it automatically outputs flag signals.  
Thereafter, output controller 1106 passes to the IDLE  
35 state where it awaits more packet data in buffer 1104 to  
be outputted. If there is packet data in buffer 104,  
the IDLE state will be exited immediately.

Receive Process Module

FIG. 15 shows in simplified block diagram form details of receive process modules 113, which are employed in the access interface receiver 102 of FIG. 1.

5 The 32 time slot packetized time division multiplexed signals from an associated one of digital line interface units 112 (FIG.1) are supplied at, in this example, a 2.048 Mb/sec rate to line deformatter 1501. Line deformatter 1501 functions include removal of idle flags  
10 from the packet data stream, removal of stuffed bits from the received packet data stream, and the generation of several control signals. These control signals are a start of packet (SOP) signal, an end of packet (EOP) signal and a packet data ready (PDR) signal. Finally,  
15 digital line deformatter 1501 outputs the received packet data in an eight-bit parallel form onto bus 1507. The start of packet (SOP) signal and the end of packet (EOP) signal are supplied to input sequencer 1506. The end of packet (EOP) signal is also supplied to packet  
20 data buffer 1503. The packet data is supplied by bus 1507 to packet originate time (POT) computer and store 1502, packet data buffer 1503, packet error check and error bit store 1504 and, finally, to logical channel to destination code translation and store 1505. Each of  
25 units 1502, 1503, 1504 and 1505 is controlled by input sequencer 1506. Input sequencer 1506 also supplies a packet stored (PS) signal to output controller 1508. Packet originate time (POT) computer and store 1502 examines the received packet data in the time stamp  
30 field and calculates the packet originate time (POT), namely,  $POT = LTA - TS$ , where TS is the time stamp value from the time stamp field of the received packet and LTA is the local time upon the packet arriving in the particular one of received process modules 113. LTA is  
35 derived from the local timing unit 120 (FIG. 1). This POT value is stored during the packet interval in preparation for outputting via multiplexer 1509 to the

receive packet bus 115. Again, the use of the POT value calculated upon the arrival of a packet at a system node simplifies the time stamp computation and reduces the number of header time stamp fields, in accordance with an aspect of the invention. Multiplexer 1509 is controlled by output controller 1508. Packet data buffer 1503 simply stores all received packet data plus one flag bit which is called the end of packet flag (END). This flag bit is further used to delimit the packets upon their being outputted to receive packet bus 115. The stored packet data is supplied to multiplexer 1509 for outputting under control of output controller 1508. The end of current packet (END) signal is also supplied from packet data buffer 1503 to output controller 1508.

Packet data in the packet header is also provided to packet error check and error bit store 1504 via bus 1507. This unit generates a cyclic redundancy code (CRC) check of the packet header in order to detect any bit errors in transmission. A signal ERR is outputted from packet error check and error bit store 1504, which is an indication of whether or not the packet data is in error. This ERR signal is used to drop the entire packet if there is an error. The ERR signal is supplied to one input of disregard packet unit 1510. Finally, the packet data is also supplied from line deformatter 1501 to the logical channel to destination code translation and store 1505. This unit examines the received logical channel number (LCN) and uses the value of the received LCN to determine the one of receive access modules 116 to which the received packet must be supplied. The LCN is translated to the destination code value which is stored during packet reception and outputted to multiplexer 1509 during packet playback to the appropriate one of receive access modules 116. Also supplied to multiplexer 1509 is the receive process module address. Output controller 1508

controls inserting the POT value into the time stamp field and the generation of the destination code process module address fields as well as the outputting of the packets to receive packet bus 115. The outputting of packets is obtained by interaction with receive bus controller 114 (FIG. 1). To this end, packet ready request signals are supplied to receive bus controller 114 and corresponding send packet signals are received from bus controller 114. The operation of bus controller 114 is identical to that of bus controller 107 described above.

FIG. 16 is a state diagram illustrating the operation of input sequencer 1506. The state diagram is entered from system reset into the IDLE state. Input sequencer 1506 remains in this IDLE state as long as there is no packet data provided from the digital line interface to line deformatter 1501. The indication that a packet is arriving is the start of packet (SOP) signal. When the start of packet (SOP) signal is true, i.e., a logical 1, and the packet data is ready, as indicated by the packet data ready (PDR) signal being a logical 1, input sequencer 1506 passes to the NEW PACKET state. In the NEW PACKET state, input sequencer 1506 enables packet data buffer 1503 to store the entire packet as it comes in and to continue storing the packet until it is finished, as evidenced by the end of packet (EOP) signal. At this time packet error check and error bit store 1504 is also enabled to begin calculation of the header check sequence. When the packet data ready (PDR) signal is again true, input sequencer 1506 passes into the LOGICAL CHANNEL NUMBER (LCN) state. In this LCN state, both packet data buffer 1503 writing, as well as logical channel to destination code translation and store 1505 operation, are enabled. Input sequencer 1506 remain in the LCN state for two data bytes, passing back to the LCN state when packet data ready PDR) is true again. During this time, logical channel to destination

code translation and store 1505 is latching the entire logical channel number (LCN) from the packet header, which takes two data bytes. Following the logical channel number (LCN), the next packet data ready (PDR) signal signal causes input sequence 1506 to pass to the PACKET ORIGINATE TIME (POT) ENABLE state. When the packet originate time (POT) is available, input sequencer 1506 enables the POT computer and store 1502 to latch the time stamp field as it comes in on the packet. POT computer and store 1502 now has all the data necessary to calculate the packet originate time (POT) as described above. When the next data byte is available, as indicated by the packet data ready (PDR) signal being true again, input sequencer 1506 passes to the STORE DATA state. Input sequencer 1506 remains in the STORE DATA state until the occurrence of one of several possible events. The first event which could occur is that the header check sequence (HCS) has appeared on bus 1507. Upon the header check sequence (HCS) appearing on bus 1507, packet error check and error bit store 1504 receives the header check sequence (HCS) and finalizes calculation of the error bits ERR. Following the header check sequence, the next packet data ready (PDR) signal indicates that part of the information field of the packet is available. Input sequencer 1506 returns to the STORE DATA state and remains there until the rest of the information field of the packet is stored. Input sequencer 1506 leaves the STORE DATA state when the end of packet (EOP) signal is true, as well as the packet data ready (PDR) signal being true and passes to the END OF PACKET state where the final data byte of the current packet is stored in packet data buffer 1503. As this time, upon reception of the inverses of packet data ready PDR start of packet SOP and end of packet EOP packet data buffer 1503 is disabled and input sequencer 1506 outputs the packet stored (PS) signal and returns to the IDLE state,

waiting for another input packet.

The packet output process of receive process modules 113 operates as follows: During packet input, the POT computer and store 1502, packet error check and error bit store 1504 and logical channel to destination code translation and store 1505 all compute results based on the current input packet header. These results are available for outputting in serial form and are remultiplexed into the packet in the appropriate fields by multiplexer 1509 under control of output controller 1508. During the packet output cycle, output controller 1508 controls both multiplexer 1509 and packet data buffer 1503 by enabling or disabling the respective read controls. If a received packet includes errors, the error bit ERR from packet error check and error bit store 1504 is used to inhibit the packet data from passing to receive packet bus 115 by enabling disregard packet unit 1510. If the packet is indeed in error, a string of zeros will be supplied to receive packet bus 115 in place of the packet.

The operation of output controller 1508 in effecting the packet output process is illustrated in the state diagrams of FIGs. 17 and 18.

FIG. 17 shows a state diagram of the interaction of output controller 1508 with bus controller 114 (FIG. 1). The state diagram is entered into the IDLE state from system reset. When the packet stored (PS) signal from input sequencer 1506 is true, output controller 1508 passes to the RECEIVE PACKET (RPR) READY state. At this time the packet ready signal going to bus controller 114 is asserted. On the following system clock (CLK) pulse, output controller 1508 passes back to the IDLE state.

FIG. 18 shows a state diagram illustrating operation of output controller 1508 in controlling the outputting of packets from receive process modules 113 to receive packet bus 115. The packet output process is

operated for the most part synchronously with the system clock so the following description of the operation of output controller 1506 will indicate operations occurring on successive clock pulses. Output controller 5 1508 enters the IDLE state from system reset. As long as there are no packets stored in packet data buffer 1503 to be outputted, output controller 1508 remains in the IDLE state. Upon reception of a receive send packet (RSP) signal from bus controller 114, output controller 10 1508 passes from the IDLE state to the SEIZE BUS state during which receive packet bus 115 is seized for outputting a packet and packet data buffer 1503 is enabled for reading. This is achieved in well-known fashion by a signal on the receive packet window bus. 15 During the next two clock (CLK) pulses, i.e., the output time for the first two packet header fields, multiplexer 1509 is enabled to supply the internal destination code to receive packet bus 115. This is done during the DESTINATION FIELD state and the SRC FIELD state. On the 20 next clock (CLK) pulse following the internal destination code field, multiplexer 1509 is enabled to supply the process module address to the receive packet bus 115. After outputting the receive process module address, the next clock pulse (CLK) causes output 25 controller 1508 to pass into the DATA OUTPUT state where most of the packet data is outputted onto receive packet bus 115. At the time when the time stamp (TS) field is available to be outputted to receive packet bus 115, however, output controller 1508 passes to the PACKET 30 ORIGINATE TIME (POT) state and enables multiplexer 1509 to output the POT result stored in POT computer and store 1502. Upon the following clock (CLK) pulse, output controller 1508 returns to the PACKET OUTPUT state and will remain there for successive system clock 35 (CLK) pulses until the remainder of the current packet is outputted from packet data buffer 1503 to receive packet bus 115. When the END signal from packet data

0234860

buffer 1503 is true, which indicates the end of the current packet being outputted therefrom, and on the next clock (CLK) pulse, output controller 1508 passes to the BUS RELEASE state. In this BUS RELEASE state, the final byte of the current packet is outputted from packet data buffer 1503 to receive packet bus 115 and receive packet bus 115 is released for use by another one of receive process modules 113. During this BUS RELEASE state the output controller 1508 is also reset and, on the following clock (CLK) pulse, the output controller 1508 passes back to the IDLE state.

#### Receive Access Module

FIG. 19 shows in simplified block diagram form details of receive access modules 116 employed in the access interface receiver 102 of FIG. 1. It is noted, that packets experience both fixed and random delays in a packet network. In reconstructing digital samples from packets it is important that the effects of the random delays be minimized in order to eliminate gaps and the like from resulting in the reconstructed signals. This is achieved, in individual ones of receive access modules 116 by adjusting the delay experienced by each of the packets to some fixed overall delay ( $D_0$ ) interval. The fixed overall delay interval comprises a known fixed delay ( $D_F$ ) interval caused by transmission and processing of the packets, a random delay (TS) interval measured by employing the unique time stamp technique, and an adjustable delay (D) interval for building out the random delay interval to a known fixed build out delay (BLD) interval. That is,  $(TS + D) + D_F = D_0$ , where  $TS + D = BLD$ . In a specific example,  $D_0 = 44$  milliseconds,  $D_F = 24$  milliseconds and  $BLD = 20$  milliseconds. Accordingly, shown are packet disassembler 1901 and decoder 1902. Included in packet disassembler 1901 is receive packet buffer and reformatter 1903, BDI to receive status translator 1904, noise estimate latch 1905, sequence number

0234860

processor 1906, packet originate time (POT) processor  
and buildout delay register 1907 and access time  
slot (ATS) latch 1908 all of which receive packet data  
from receive packet bus 115. The local time signal from  
5 local timing unit 120 (FIG. 1) is supplied to  
POT processor and buildout delay register 1907 and to  
receive ATS sequencer 1911. The receive packet window  
bus from receive packet bus 115 is supplied to receive  
packet bus sequencer 1910. Also supplied to receive  
10 packet bus sequencer 1910 is the packet data from  
receive packet bus 115, a packet length signal from BDI  
to receive status translator 1904, a late packet  
indication from POT processor and buildout delay  
register 1907, an internal destination address from the  
15 receive access module back-plane and the access time  
slot signal (ATS) from ATS latch 1908. Receive packet  
bus sequencer 1910 supplies a plurality of control  
signals to receive packet buffer and reformatter 1903.  
Specifically, the control signals include a write (WRT)  
20 signal, a memory bank select (BANK SEL) signal and a  
write address (WRT ADDR) signal. Additionally, receive  
packet bus sequencer 1910 supplies a start address (SA)  
signal (same as WRT ADDR) and a parameter buffer write  
control signal (PBWRT) to parameter buffer 1909. The  
25 start address (SA) signal indicates the memory location  
in receive packet buffer and reformatter 1903 in which  
the first sample is stored of the current packet in the  
current time slot. Although not specifically shown,  
receive packet bus sequencer 1910 supplies control  
30 signals to each of BDI to receive status  
translator 1904, noise estimate latch 1905, sequence  
number processor 1906, POT processor and buildout delay  
register 1907 and ATS latch 1908 for effecting control  
of those units, as will be described below. Parameter  
35 buffer 1909 is a first-in first-out (FIFO) type buffer  
which stores relevant information from the packet header  
that is used by receive access time slot (ATS)

sequencer 1911 for controlling the outputting of reformatting packet data from receive packet buffer and reformatter 1903. To this end, a receive status (RS) signal is supplied to buffer 1909 from BDI to receive status translator 1904; a background noise estimate (NE) signal is supplied from noise estimate latch 1905; a packet playout time (PPT) signal is supplied from POT processor and buildout delay 1907; a cat/sched (C/S) control signal is supplied from sequence number processor 1906; and finally, the ATS control signal is supplied from ATS latch 1908. As indicated above, parameter buffer 1909 stores this plurality of signals for use by receive ATS sequencer 1911 for outputting data from receive packet buffer and reformatter 1903 in the appropriate PCM or ADPCM format. Accordingly, the receive status (RS) signal, the noise estimate (NE) signal, the start address (SA) signal, the packet playout time (PPT) signal, the cat/sched (C/S) signal, the ATS signal and an additional signal (EMPTY) which indicates that parameter buffer 1909 is empty are supplied to receive ATS sequencer 1911. If the Empty signal is true, i.e., a logical 1, parameter buffer 1909 is empty and there are no packets to be processed in receive packet buffer and reformatter 1903. Additionally, the receive status (RS) signal and the noise estimate (NE) signal are supplied to multiplexer 1912. A local time signal from local timing unit 120 (FIG. 1) is also supplied to receive ATS sequencer 1911.

Receive ATS sequencer 1911 operates to control the outputting of reformatting data from packet disassembler 1901. To this end, it generates a signal for controlling multiplexer 1912 to supply the receive status and noise estimate signals at the appropriate times to decoder 1902 for use, as will be described below in the decoder 1902 description. Receive ATS sequencer 1911 also generates a packet active signal

which is also supplied to decoder 1902 for use as will be described below. To control the outputting of reformatted data from receive packet buffer and reformatter 1903, receive ATS sequencer 1911 supplies thereto a read (RD) signal, a read address (RD ADDR) signal and a read memory bank select (RD BANK SEL) signal. Operation of receive ATS sequencer 1911 is described below in conjunction with the state diagram in FIG. 23.

- 10 BDI to receive status translator 1904 includes a latch memory and read only memory unit (ROM) (not shown). The incoming BDI field is employed as an address to the ROM which provides the receive status (RS) signal and the packet length signal.
- 15 Specifically, the receive status signal indicates the type of coding which was employed in the corresponding access interface transmitter. For example, whether it was 8-bit PCM coding, embedded ADPCM coding, that is, 4/3-bits embedded coding, 4/2-bits embedded coding, or
- 20 3/2-bits embedded coding, four-bit ADPCM, three-bit ADPCM or two-bit ADPCM. The length signal indicates the length of the packet to be played out of packet disassembler 1901, i.e., whether or not any of the enhancement bit fields have been dropped for the
- 25 embedded coding packets.

Noise estimate latch 1905 is a four-bit memory which stores a background noise estimate from the receive packet header.

- Sequence number processor 1906 includes a
- 30 latch memory unit, a virtual sequence counter and control logic (not shown) to generate the so-called cat/sched (C/S) signal, in accordance with an aspect of the invention. If the packet is an initial packet of a speech spurt, this packet must be scheduled for playout
- 35 according to the packet playout time generated by POT processor and buildout delay register 1907. The identification of a packet as the initial packet in an

information spurt is obtained by advantageously employing the unique virtual sequence number scheme, in accordance with an aspect of the invention. As indicated above, the virtual sequence includes a continuous sequence of numbers not including the unique number used to identify the initial packet in the information spurt. If it is not an initial packet, the packet is concatenated with the previous packet for playout. If one or more packets have been lost prior to receiving this particular packet, sequence number processor 1906 will schedule the current packet for playout, also according to the packet playout time generated by POT processor and buildout delay register 1907.

FIG. 20 is a flow chart illustrating the steps of the control logic of sequence number processor 1906 in generating the cat/sched (C/S) signal. Accordingly, the sequence is entered via 2001 for each packet processed by this particular receive access module 116.

Thereafter, conditional branch point 2002 tests to determine whether the sequence number is the unique number reserved to identify the initial packet in the information spurt, in this example, zero (0). If the test result in step 2002 is YES, operational block 2003 causes the virtual sequence counter to be incremented. Since the test result in step 2002 was YES, indicating that the packet is the initial packet in a speech spurt, operational block 2004 sets the cat/sched (C/S) signal to sched, which will cause the playout of this initial packet to be scheduled according to the packet playout time (PPT) generated in POT processor and buildout delay 1907. The operational block 2005 causes the cat/sched (C/S) signal to be outputted to parameter buffer 1909. Thereafter, the sequence is exited via 2006. Returning to step 2002, if the test result therein is NO, the packet virtual sequence number is not zero (0), which indicates that it is not an initial

packet in an information spurt and conditional branch point 2007 tests to determine whether the sequence number is equal to the value in the virtual sequence counter plus one. The test in step 2007 is to determine  
5 whether or not the current packet being processed follows a lost packet or not, in accordance with an aspect of the invention. If the test result is YES, this packet does not follow a lost packet and operational block 2008 causes the virtual sequence  
10 counter to be incremented. Operational block 2009 causes the cat/sched (C/S) signal to be set to cat. Thereafter, operational block 2005 causes the cat/sched (C/S) signal to be outputted to parameter buffer 1909. The sequence is thereafter exited via 2006. Returning  
15 to step 2007, if the test result therein is NO, indicating that the current packet has followed a lost packet, operational block 2010 causes the virtual sequence counter to be set to the sequence number of the current packet. The next processed packet, if there is  
20 one in the information spurt, would be a cat packet which is concatenated on the current scheduled packet. Operational block 2011 causes the cat/sched indication to be set to sched since the current packet requires to be scheduled for playout according to the packet playout  
25 time generated by POT processor and buildout delay 1907. That is to say, the current packet that has followed a lost packet is considered to be an initial packet and treated as such. Thereafter, operational block 2005 causes the cat/sched bit to be outputted to parameter  
30 buffer 1909. The process is thereafter exited via 2006.

POT processor and buildout delay register 1907 includes a latch memory for storing the POT field from the packet header and control logic( not shown) for generating the packet playout time (PPT) and the late  
35 packet indication. Also included is a register to provide the programmed system buildout delay for the packet. The packet playout time (PPT) is a local time

value when a first sample from a corresponding packet information field is to be read from receive packet buffer and reformatter 1903. The packet playout time is computed so that the packet data experiences the desired fixed overall delay ( $D_0$ ). This fixed overall delay is realized by uniquely employing the packet originate time (POT) value and the buildout delay (BLD) value. As indicated above, the randomness of the delay experienced by the packet is eliminated by "building out" the delay to a known value. Then, the fixed overall delay is obtained by outputting the first sample of the packet information field at the local time value equal to the packet playout time (PPT) value, namely  $PPT = POT + BLD$ , where  $POT = LTA - TS$ .

FIG. 21 is a flow chart of the sequence of steps effected by the control logic of POT processor and buildout delay register 1907 in generating the packet playout time (PPT) signal and the late packet indication signal. Accordingly, the sequence is entered via 2101 for each packet processed by this particular receive process module 116. Thereafter, operational block 2102 generates a temporary variable,  $TEMP1$ , which is the algebraic difference between the packet originate time value from the packet header time stamp field less the local time obtained from the local timing unit 120, i.e.,  $TEMP1 = POT - LT$ . Conditional branch point 2103 performs a test to determine whether or not the arithmetic for generating the time stamp value is correct. In this example, the test is whether  $TEMP1$  is a value in the range equal to or greater than 1 and equal to or less than 128. This test checks whether or not the arithmetic in calculating the packet playout time has overflowed. If the arithmetic has overflowed, any results obtained therefrom would be erroneous. If the test result in step 2103 is NO, the arithmetic has overflowed and operational block 2104 causes the late packet signal to be set to true, i.e., to a logical 1.

Thereafter, operational block 2105 causes the outputting of the true late packet signal. The process is then exited via 2106. If the test in step 2103 yields a YES result, the arithmetic has not overflowed and

5 operational block 2107 calculates the packet playout time (PPT) which is equal to the packet originate time (POT) plus the system buildout delay (BLD), i.e.,  $PPT = POT + BLD$ . The POT(n) currently being generated is  $POT(n) = LTA(n) - TS(n-1)$ , where LTA(n) is the packet

10 arrival time of the current packet and TS(n-1) is the time stamp value from the time stamp field in the header of the currently arriving packet, and the current time stamp value TS(n) being generated is  $TS(n) = LTD(n) - POT(n)$ , where LTD(n) is the current packet departure

15 time from the node. Operational block 2108 generates another temporary variable TEMP2, which is equal to the local time minus the packet playout time, i.e.,  $TEMP2 = LT - PPT$ . TEMP2 is used to determine if the packet is late relative to the system buildout delay. To this

20 end, conditional branch point 2109 tests the TEMP2 variable to determine whether TEMP2 is within predetermined limits. In this example, the test is whether TEMP2 is a value within the range of equal to or greater than 1, and equal to or less than 128. If the

25 test result in step 2109 is NO, the current packet is late relative to the system buildout delay and operational block 2104 sets the late packet indication to be true. Thereafter, operational block 2105 again outputs the late packet true indication. Then, the

30 sequence is exited via 2106. If the test result in step 2109 is YES, the packet is not late relative to the buildout delay and operational block 2110 sets the late packet indication to be false, i.e., a logical 0. Operational block 2105 causes the packet playout time

35 signal and the late packet false indication to be outputted. Again, the sequence is outputted via 2106.

ATS latch 1908 is simply a latch memory which stores the ATS portion of the internal destination code field of the packet header.

Receive packet buffer and reformatter 1903 includes a plurality of memory units (not shown) for appropriately storing the bits of the packet information fields. Specifically, the memory units are arranged to separately store packet data in odd and even time slots. Each of these memory units includes storage elements for storing, for example, all the sign bits, all the (1) bits, all the (2) bits, etc., or all the sign (s) bits, all the (a) bits, all the (b) bits, etc., through the number of bits used in the particular packet. In this example, the maximum number of bits is 8 including the sign bit. Writing the received packet information field bits into the receive packet buffer and reformatter 1903 is controlled by receive packet bus sequencer 1910, which will be described in conjunction with the state diagram shown in FIG. 22. The so-called reformatting of the packet information fields is effected in the reading out of the data from the memory units under control of receive ATS sequencer 1911, which operation will be described in conjunction with the state diagram shown in FIG. 23. As indicated above, the packet information field in either of the formats shown in FIGs. 3 or 4 is written into receive packet buffer and reformatter 1903 and the data is reformatted into the desired PCM or ADPCM format upon reading the data out therefrom. This is realized by proper selection of the write and read address lines of receive packet buffer and reformatter 1903. It is noted that if the reformatted PCM sample is 8-bit PCM, then decoder 1902 is by-passed (not shown) in well known fashion.

FIG. 22 shows a state diagram illustrating the sequence of steps of the operation of receive packet bus sequencer 1910 in effecting writing of received packet data into receive packet buffer and reformatter 1903 and

writing of the packet parameters into parameter  
buffer 1909. Accordingly, the IDLE state is entered  
from system reset. While in the IDLE state, the  
following actions are performed: processing of the  
5 packets is disabled on the input side to receive packet  
buffer and reformatter 1903, and receive packet bus  
sequencer 1910 waits for a receive window (RW) bus  
active indication from receive packet bus 115 indicating  
that a packet is proceeding to be outputted onto receive  
10 packet bus 115. When the receive window bus becomes  
active, receive packet bus sequencer 1910 passes to the  
MATCH state. In the MATCH state, receive packet bus  
sequencer 1910 checks the destination code field of the  
incoming packet against the destination address supplied  
15 to this particular one of receive access modules 116  
from the back-plane. If there is no match, the receive  
packet bus sequencer 1910 remains in the MATCH state  
waiting for the receive window bus to become inactive.  
No further processing is effected on this packet since  
20 the packet is destined for some other one of receive  
access modules 116. When the receive window bus becomes  
inactive, the receive packet bus sequencer 1910 returns  
to the IDLE state waiting once again for another packet  
to be outputted onto the receive packet bus 115. If the  
25 destination code field matches the supplied destination  
address, receive packet bus sequencer 1910 waits until  
the ATS field is available. When the ATS field is  
available, the ATS state is entered and the ATS field is  
latched in ATS latch 1908. If the receive packet window  
30 bus becomes inactive, receive packet bus sequencer 1910  
returns to the IDLE state. When the time stamp field is  
available receive packet bus sequencer 1910 passes to  
the TS LATCH state. In the TS LATCH state the time  
stamp information is latched into POT processor and  
35 buildout delay 1907, and the POT processor is enabled to  
calculate the packet playout time and the late packet or  
on-time packet indication. If the packet is late, the

0234860

processing halts at this point causing the packet to be discarded and the receive packet bus sequencer 1910 remains in the TS LATCH state until the receive window bus once again becomes inactive. At that time, receive  
5 packet bus sequencer 1910 passes back to the IDLE state to wait for the next packet. If the packet is not late, the receive packet bus sequencer 1910 waits in the TS LATCH state until the bit dropping indicator (BDI) field is available. When the BDI field is available, the  
10 receive packet bus sequencer 1910 passes to the BDI LATCH state. In the BDI LATCH state, the received BDI is latched in BDI to receive status translator 1904 which is enabled in order to determine the receive status and length information for the following part of  
15 the packet. If for some reason the receive window bus becomes inactive while BDI processing is taking place, the receive packet bus sequencer 1910 once again passes back to the IDLE state and waits for another packet. No status information or data is written into either  
20 receive packet buffer and reformatter 1903 or parameter buffer 1909. When the noise estimate (NE) field becomes available, the receive packet bus sequencer 1910 passes from the BDI LATCH state to the NOISE ESTIMATE and SEQUENCE NUMBER LATCH state. While in this state,  
25 receive packet bus sequencer 1910 causes the noise estimate and the sequence number field to be latched and causes the sequence number processing to be enabled in order to determine whether or not this packet is a concatenate packet or a scheduled packet. A counter is  
30 also loaded at this time with the length value of the packet which was obtained in the BDI LATCH state and was provided to receive packet bus sequencer 1910 by BDI to receive status translator 1904. This length value indicates whether any one or more of the enhancement bit  
35 fields have been dropped from the packet information field. When the packet information field begins, receive packet bus sequencer 1910 passes to the WRITE

5 BUFFERS state. Upon entry into the WRITE BUFFERS state,  
all the processed results of the header processing are  
written into the parameter buffer 1909. The buffer  
writing is enabled by the write signal (PBWRT) which is  
10 supplied to parameter buffer 1909. While in the WRITE  
BUFFERS state, receive packet buffer and  
reformatter 1903 is enabled via a write (WRT) signal so  
that the information field of the packet may be written.  
Receive packet bus sequencer 1910 also provides the  
15 write address (WRT ADDR) to receive packet buffer 1903  
so that the byte of data being written may be stored in  
an appropriate memory location associated with the  
particular time slot that the packet is being  
transmitted in. When each byte of the information field  
20 is available, a counter (C) in receive packet bus  
sequencer 1910 is decremented until it finally times  
out. When the receive window bus becomes inactive  
because of the end of a packet or the counter C times  
out to the appropriate length of the packet, the writing  
25 of receive packet buffer and reformatter 1903 is  
disabled and the receive packet bus sequencer 1910  
passes back to the IDLE state waiting for the next  
packet.

FIG. 23 depicts a state diagram illustrating  
25 the sequence of steps in the operation of receive  
ATS sequencer 1911 in controlling reading packet data  
from receive packet buffer and reformatter 1903 and  
controlling the operation of multiplexer 1912 in  
supplying information to decoder 1902. Accordingly, the  
30 IDLE state of the sequence is entered on system reset.  
While in the IDLE state, all processing of packet output  
data from receive packet buffer and reformatter 1903 is  
disabled. Receive ATS sequencer 1911 also controls  
operation of multiplexer 1912 to set the receive  
35 allocation to the noise estimate (NE) from the previous  
packet during silent intervals and sets the receive  
packet data from receive packet buffer and

0234860

reformatter 1903 to all zeros during the time slot that noise is to be inserted. When parameter buffer 1909 supplies a not-empty indication to receive  
ATS sequencer 1911, it passes to the WAIT state. While  
5 in the WAIT state, receive ATS sequencer 1911 first reads parameter buffer 1909 values for the packet which is being prepared for playout. Receive  
ATS sequencer 1911 sets the receive allocation to the noise estimate (NE) as read from parameter buffer 1909  
10 and sets the packet active indication to inactive for this access time slot (ATS). The receive data from receive packet buffer and reformatter 1903 is made all zeros during this time slot since it is an inactive time. Receive packet buffer 1903 read address is  
15 initialized for this packet and receive  
ATS sequencer 1911 waits for the local time to equal the packet playout time as read from parameter buffer 1909. When the packet playout time is reached, receive  
ATS sequencer 1911 passes to the PLAYOUT state. While  
20 in the PLAYOUT state, receive ATS sequencer 1911 performs the following functions: packet buffer and reformatter 1903 is enabled for reading out packet data; the read address is supplied to receive packet buffer and reformatter 1903 for this access time slot (ATS);  
25 the receive allocation is set to the receive status (RS) as read from parameter buffer 1909; the packet active signal is set to active (true) for this ATS; receive packet buffer and reformatter 1903 address is incremented and managed while the packet playout is  
30 underway; and, finally, the PLAYOUT state is maintained until receive packet buffer and reformatter 1903 address reaches 127, i.e., until the next to last sample of the packet has been played out. As indicated above, there are 128 samples in a packet interval. When the next to  
35 last sample of the packet has been played out of receive packet buffer and reformatter 1903, receive  
ATS sequencer 1911 passes to the LAST PLAYOUT state.

During the LAST PLAYOUT state, the last sample of this packet is read from receive packet buffer and reformatter 1903 by providing the read address, read enable and memory bank select signals thereto, and

5 processing of the next packet in the sequence of the speech spurt begins. The receive allocation is set to the receive status from parameter buffer 1909 for as in playing out the other samples of the packet. Finally, parameter buffer 1909 empty signal is checked to

10 determine whether there is another packet to be played out or not. If there is another packet to be played out, the cat/sched (C/S) signal is interrogated to determine whether receive ATS sequencer 1911 must pass back to the WAIT state or back to the PLAYOUT state. If

15 the cat/sched (C/S) signal indicates that the next packet is a concatenate packet, receive ATS sequencer 1911 returns to the PLAYOUT state and concatenates the packet to be played out to the packet which was just played out. If the cat/sched (C/S)

20 signal indicates that this is a schedule packet but the playout time has not yet been reached, receive ATS sequencer 1911 passes back to the WAIT state in order to wait for the playout time to be achieved. If parameter buffer 1909 is empty, this indicates that no

25 more packets are available for playout on this ATS and receive ATS sequencer 1911 passes back to the IDLE state waiting for more packets to be processed. Again, in this example the samples are read out of receive packet buffer and reformatter 1903 in either the 8-bit PCM

30 format or the ADPCM format of FIG. 3 and FIG. 4, respectively.

FIG. 24 shows in graphical form the generation of individual packets in a speech spurt in transmitter 101 and the recovery of those generated

35 packets in receiver 102. As shown, the packets are generated in access interface transmitter 101 at the packet originate interval ( $t_0$ ) which in this example is

16 milliseconds. The transmitted packets are received at access interface receiver 102 at arbitrary intervals with random transmission delays as indicated by the packet receive time ( $t_r$ ). Then, shown is the attempted equalization of the random delays caused in the transmission of the packets as indicated by the packet playout time ( $t_p$ ). As shown, the playout time of the initial packet in the speech spurt is built out to the network buildout delay (BLD). Upon playout of the initial packet, the subsequent packets are played out at the packet originate interval ( $t_o$ ), which is, in this example, 16 milliseconds, for packets in a continuous information spurt and also providing that they are not determined to be late packets. In this example, if the packet arrives late, it is discarded. As indicated in FIG. 24, packet 4 is late and is discarded. Thereafter, packet 5 is played out as a scheduled packet by the packet disassembler.

#### Encoder

FIG. 25 shows in simplified block diagram form details of encoder 204 employed in voice processing module 201 of FIG. 2. Encoder 204 is employed to encode voiceband PCM signals, i.e., speech, voiceband data and tones into ADPCM signals. In this example, 8-bit  $\mu$ -law PCM signals are converted to linear form and, then, encoded into one of several possible ADPCM signals. For example, linear PCM samples may be converted into 4 bit, 3 bit or 2 bit ADPCM samples. Additionally, the ADPCM samples may include so-called embedded coding. For example, the output samples may be 4/2-bit embedded coding, 4/2-bit embedded coding or 3/2-bit embedded coding. As indicated above, such coding arrangements are known in the art. See, for example, U.S. patent 4,437,087 issued March 13, 1984 for an adaptive ADPCM coding arrangement. Also, see U.S. patent 4,519,073 issued May 21, 1985 for a variable rate adaptive ADPCM coding arrangement.

Accordingly, in FIG. 25 linear PCM samples  $s_1(k)$  are supplied to a plus (+) input of difference circuit 2501 and a sample estimate  $s_e(k)$  is supplied from adaptive predictor 2506 to a minus (-) input of difference circuit 2501 which generates a difference sample  $d(k)$ . Difference sample  $d(k)$  is supplied to variable rate quantizer 2502 which, under control of a control signal supplied via bit rate controller from controller 207 (FIG. 2), generates the ADPCM output sample  $I(k)$ . Variable rate quantizer 2502, in this example, includes three separate adaptive quantizers for generating either the 4-bit, 3-bit or 2-bit ADPCM sample  $I(k)$  under control of controller 207 (FIG. 2). Such adaptive quantizers are known in the art. See, for example, CCITT Recommendation G.721 "32 kbit/s Adaptive Differential Pulse Code Modulation (ADPCM)", VIIIth CCITT Plenary Assembly, Malaga-Torremolinos, Spain, Vol. 111, pp. 125-159, October 1984, for one such adaptive quantizer. The ADPCM sample  $I(k)$  is supplied to quantizer adaptation unit 2503, variable rate inverse quantizer 2504 and to packet assembler 202 (FIG. 2). Variable rate inverse quantizer 2504 also includes three adaptive inverse quantizers which perform the inverse functions of the adaptive quantizers of variable rate quantizer 2502 and generate a quantized version of the difference sample, namely,  $d_q(k)$ . Again, the particular one of the inverse quantizers that is used is under control of control signals supplied via bit rate controller 2510 from controller 207 (FIG. 2). The adaptive inverse quantizers are, in this example, 4-bit, 3-bit and 2-bit and are selected depending on the particular coding being used. For example, if 4/2-bit embedded coding is being used in a particular time slot, a 4-bit adaptive quantizer is selected in variable rate quantizer 2502 and a 2-bit variable rate adaptive inverse quantizer is selected in variable rate inverse quantizer 2504. An

example of an adaptive inverse quantizer that may be employed in variable rate inverse quantizer 2504 is disclosed in the CCITT Recommendation G.721 cited above. The quantized version of the difference sample  $d_q(k)$  is  
5 supplied to one input of summing circuit 2505 and the sample estimate is supplied to another input of summing circuit 2505 which provides the algebraic sum thereof at its output, namely, reconstructed sample  $s_r(k)$ . The reconstructed sample  $s_r(k)$  is supplied to adaptive  
10 predictor 2506. Adaptive predictor 2506 generates estimate sample  $s_e(k)$  which is an estimate of the linear PCM input sample  $s_1(k)$ . One such adaptive predictor is also disclosed in the CCITT Recommendation G.721 cited above. Variable rate quantizer adaptation unit 2503  
15 generates the quantizer and inverse quantizer adaptation scale factors  $y_a(k)$  and  $y_b(k)$ , respectively. Scale factor  $y_a(k)$  is supplied to the variable rate quantizer 2502 and scale factor  $y_b(k)$  is supplied to variable rate inverse quantizer 2504. Again, variable  
20 rate quantizer adaptation unit 2503 includes three quantizer adaptation units, in this example, one for 4-bit, one for 3-bit and one for 2-bit quantization. The selection of the particular one or ones of the quantizer adaptation units is also under control of control  
25 signals supplied via bit rate controller 2510 from controller 207 (FIG. 2). By way of an example, if 4/2-bit embedded coding is being used, 4-bit scale factor  $y_a(k)$  adaptation is selected for variable rate quantizer 2502, and 2-bit scale factor  $y_b(k)$  adaptation  
30 is selected for variable rate inverse quantizer 2504. As is apparent, the scale factor adaptation selected under control of controller 207 has to match the adaptive quantizer selected in variable rate quantizer 2502 and also the inverse adaptive quantizer  
35 selected in variable rate inverse quantizer 2504. One such quantizer adaptation unit including an adaptation speed control and a quantizer scale factor adaptation

unit is disclosed in the CCITT Recommendation G.721 cited above.

Both variable rate quantizer adaptation unit 2503 and adaptive predictor 2506 have so-called state variables that are updated in the adaptation process. For simplicity and clarity of description, these are illustrated as being in state variables unit 2507. Typically, such state variables are stored in memory locations (not shown) and are updated during each sample interval ( $k$ ). It will be apparent to those skilled in the art that variable rate quantizer adaptation unit 2503 state variables are contained in the adaptation speed control and the quantizer scale factor adaptation unit in the individual quantizer adaptation units used therein and that the predictor 2506 state variables are the predictor coefficients. These state variables may be initialized by setting the values in the memory locations to prescribed values and may be held constant by inhibiting updating of the stored values in well known fashion. In this example, the state variables in the scale factor adaptation units are those for DELAYB and DELAYC (see pages 138-139 of the CCITT Recommendation G.721 cited above) and in the adaptation speed control units the one for DELAYA (see page 141 of the CCITT recommendation G.721). The state variable values for the adaptive predictor 2506 are the predictor coefficients. These state variables are also disclosed in the CCITT Recommendation G.721 cited above.

Also included in encoder 204 are control elements for controlling the encoder state variables, in accordance with an aspect of the invention, in order to recover from transmission errors and lost packets, and to minimize the effects of artificial gaps in the receive information. In accordance with one aspect of the invention, the values of the state variables are held constant, i. e., not updated, upon the particular

0234860

transmission channel activity becoming inactive until a predetermined interval has elapsed or the transmission channel status becomes active, whichever occurs first. If the transmission channel status becomes active before  
5 the predetermined interval has elapsed, the hold state is terminated and adaptation of the state variables resumes. If the predetermined interval elapses, then the state variables are initialized to prescribed values. Again, the state variables to be initialized  
10 are contained in variable rate quantizer adaptation unit 2503 and in adaptive predictor 2506. It is noted that the state variables are actually contained in adaptation speed control units and quantizer scale factor adaptation units within the particular quantizer  
15 adaptation units comprising variable rate quantizer adaptation unit 2503. Particular values of the state variables are disclosed in the CCITT Recommendation G.721 cited above. In this example, the initial value of state variable DELAYA in the adaptation  
20 speed control is zero (0), the initial values of state variables DELAYB and DELAYC in the quantizer scale factor adaptation unit are digital 544 and digital 34816, respectively, and the predictor coefficients are initialized to zero (0) values.

25       The control of the state variables is realized by supplying the packet active signal from controller 207 (FIG. 2) to enable/hold decoder 2508. Enable/hold decoder 2508, in response to a true, i.e., logical 1, packet active signal, indicating a packet is  
30 being processed in a particular time slot, generates a true operate signal, a true counter reset signal and a false, i.e., logical 0, counter enable signal. When the packet active signal is false, enable/hold decoder 2508 generates a false operate signal and counter reset  
35 signal and a true counter enable signal. The operate signal is supplied to state variables unit 2507 for inhibiting, resetting or enabling their adaptation as

0234860

necessary. The counter reset signal is supplied to frame counter 2509 and the counter enable signal is supplied to frame counter 2509 and time-out detector 2511. Counter 2509, in this example, counts at  
5 an 8 kHz rate up to 2048 which represents 256 milliseconds. If counter 2509 times out, a true output signal is generated which is supplied to time-out detector 2511. Counter 2509 is incremented for each frame that no packet is present. The count of 2048 was  
10 selected so that the state variables would not be initialized during the interval between words during normal speech. Time-out detector 2511, in response to a true counter enable signal and a false time-out signal, generates a true hold signal and a false initialize  
15 signal. When the counter enable signal and time-out signal are both true, a false hold signal and a true initialize signal are generated. When both the counter enable and time-out signals are false, time-out detector 2511 generates false hold and initialize  
20 signals. The hold and initialize signals are supplied to state variables unit 2507 to control the state variables accordingly. The reason for holding the state variables constant is to preserve the speech signal adaptation for so-called intersyllabic speech gaps.  
25 Consequently, the variables are only initialized when the gaps are greater than a predetermined interval, in this example, 2048 frames or one quarter second.

FIG. 26 is a state diagram which illustrates the encoder 204 state variables control operation.  
30 Accordingly, the INITIALIZE state is initially entered from system reset. The state variables are initialized upon the counter enable signal being true and frame counter 2509 yielding a true time-out signal, indicating it has "timed-out". Again, the state variables of the  
35 quantizer adaptation units in variable rate adaptation unit 2503 and of adaptive predictor 2506 are initialized to the values indicated above by storing those values in

0234860

appropriate memory locations. Upon the packet active signal being true, indicating a packet is being processed, the OPERATE state is entered and enable/hold decoder 2508 generates true operate and reset signals  
5 and a false counter enable signal. Consequently, adaptation of the state variables is enabled and frame counter 2509 is reset to zero (0). This OPERATE state is maintained and encoder 204 adaptation continues until  
10 the packet active signal becomes false, indicating no packet is being processed. Then, the HOLD state variables and counter enable state is entered. In this HOLD state, enable/hold decoder 2508 generates false operate and counter reset signals and a true counter enable signal. Time-out detector 2511 generates a true  
15 hold signal and a false initialize signal. Consequently, the values of the state variables are inhibited from being updated and are held constant. This HOLD state is maintained as long as there is no packet being processed and frame counter 2509 has not  
20 timed out. If a packet subsequently appeared, as indicated by the packet signal being true and the counter 2509 has not timed out, the OPERATE state is again entered and operation is as described above. If no packet is present and frame counter 2509 times out as  
25 indicated by a true time-out signal, timeout detector 2511 generates a true initialize signal and a false hold signal and the INITIALIZE state is again entered and the state variables are initialized as described above. The INITIALIZE state is maintained  
30 until a packet is again present.

#### Decoder

FIG. 27 shows in simplified block diagram form details of decoder 1902 employed in receive access modules 116 of FIG. 19. Decoder 1902 is employed to  
35 decode ADPCM signals back into PCM signals. In this example, 4-bit, 3-bit or 2-bit ADPCM samples are decoded into linear PCM form. Additionally, the ADPCM samples

may include so-called embedded coding. For example, the samples may be 4/3-bit embedded coding, 4/2-bit embedded coding or 3/2-bit embedded coding. As indicated above, such coding arrangements are known in the art. Again,  
5 see U.S. patent 4,437,087 for an adaptive ADPCM decoder arrangement.

Accordingly, in FIG. 27 the ADPCM samples  $I'(k)$  from packet disassembler 1901 (FIG. 19) are supplied to variable rate quantizer  
10 adaptation unit 2701, variable rate inverse quantizer 2702 and variable rate inverse quantizer 2703. Variable rate quantizer adaptation unit 2701 is identical to variable rate quantizer adaptation unit 2503 of encoder 204 described above and is  
15 responsive to control signals from bit rate controller 2713 to select the appropriate one or ones of the plurality quantizer adaptation units (not shown) to generate scale factor  $y'_a(k)$  and  $y'_b(k)$ .

Scale factor  $y'_a(k)$  is supplied to the  
20 selected one of the inverse quantizers in variable rate inverse quantizer 2702. Similarly, scale factor  $y'_b(k)$  is supplied to the selected one of the inverse quantizers in variable rate inverse quantizer 2703. Variable rate inverse quantizer 2702 and variable rate  
25 inverse quantizer 2703 each includes a plurality of adaptive inverse quantizers. In this example, a 4-bit adaptive inverse quantizer, a 3-bit adaptive inverse quantizer and a 2-bit adaptive inverse quantizer. Both variable rate inverse quantizer 2702 and variable rate  
30 inverse quantizer 2703 are identical to variable rate inverse quantizer 2504 of encoder 204 described above. The particular adaptive inverse quantizer used in variable rate inverse quantizer 2702 and in variable rate inverse quantizer 1703 depends on the ADPCM coding  
35 being used, i.e., 4-bit, 3-bit, 2-bit, 4/3-bit embedded coding, 4/2-bit embedded coding or 3/2-bit embedded coding. Variable rate inverse quantizer 2702 generates

a quantized version of the original difference sample  $d'_{qa}(k)$  which is supplied to summer 2704. Similarly, variable rate inverse quantizer 2703 generates a quantized version of the difference sample  $d'_{qb}(k)$ . Quantized difference samples  $d'_{qa}(k)$  and  $d'_{qb}(k)$  are the same for the 4-bit, 3-bit and 2-bit ADPCM coding but are different for the embedded coding. For example, if the ADPCM coding is 4/2-bit embedded coding, the adaptive inverse quantizer selected in variable rate inverse quantizer 2702 is a 4-bit type and the adaptive inverse quantizer selected in variable rate inverse quantizer 2703 is a 2-bit type. In this example, the packet network could drop the 2 bits which are not used in variable rate inverse quantizer 2703 without affecting operation of this inverse quantizer. It is further noted that the type of inverse quantizer, i.e., 4-bit, 3-bit or 2-bit, used in inverse variable rate inverse quantizer 2702 is dependent also on whether bits have been dropped. For example, if two bits have been dropped, then a 2-bit inverse quantizer is used in variable rate inverse quantizer 2702. The quantized difference sample  $d'_{qb}(k)$  is supplied to summer 2707. Also supplied to summers 2704 and 2707 is sample estimate  $s'_e(k)$  from adaptive predictor 2705. The output from summer 2704 is first reconstructed sample  $s'_{ra}(k)$  which is supplied to adaptive predictor 2705. The output from summer 2707 is the desired output, namely, second reconstructed sample  $s'_{rb}(k)$  which is supplied to multiplexer 2708. A noise signal from noise generator 2714 is also supplied to multiplexer 2708. The noise generator 2714 generates an appropriate noise signal in response to the noise estimate (NE) signal supplied thereto via multiplexer 2712 and the RCV allocation signal from packet disassembler 1901. The noise signal is inserted via multiplexer 2708 when the operate signal is false, i.e., when no packet is present in the particular time

slot. Again, for simplicity and clarity of description, the state variables of variable rate quantizer adaptation unit 2701 and adaptive predictor 2705 are shown as state variables unit 2706. As will be apparent

5 to those skilled in the art, the state variables of variable rate quantizer adaptation unit 2701 are included in an adaptation speed control and a quantizer scale factor adaptation unit in each of the plurality of quantizer adaptation units as described above in

10 relationship to state variables unit 2507 (FIG. 25).

Enable/hold decoder 2709, frame counter 2710 and time-out detector 2711 operate in identical fashion to enable/hold decoder 2508, frame counter 2509 and time-out detector 2511, respectively, of encoder 204

15 (FIG. 25) as shown in the state diagram of FIG. 28 and, consequently, will not be described again in detail.

The only difference being that the packet active signal and the rcv allocation signal are supplied from packet disassembler 1901. It is important to note that both

20 the encoder 204 and decoder 1902 are controlled in similar fashion to recover from errors and gaps so that the decoder 1902 tracks what has happened at the encoder 204. In particular, decoder 1902 will, in

accordance with an aspect of the invention, hold its

25 state variables constant, rather than initialize them and thereby mistrack encoder 204 if the packet

network 103 introduces a small gap in an information spurt that had been encoded without any such small gaps.

Thus, by holding the state variables decoder 1902 more

30 closely tracks encoder 204. Additionally, encoder 204

and decoder 1902 both initialize their state variables after long gaps, which eliminates, in accordance with an aspect of the invention, any mistracking caused by transmission errors or lost packets in the network.

35 Demultiplexer 2712 is supplied with the receive (RCV) allocation signal from packet disassembler 1901 and is operative to supply the receive

0234860

status (RS) portion to bit rate controller 2713 and the noise estimate (NE) portion to noise generator 2714. Bit rate controller 2713, in response to the receive status signal, generates the code rate control signals

5 for selecting (depending on the ADPCM coding being used) the appropriate quantizer adaptation unit or units in variable rate quantizer adaptation unit 2701 and the appropriate adaptive inverse quantizers in variable rate inverse quantizers 2702 and 2703. Multiplexer 2708 is

10 responsive to the operate signal from enable/hold decoder 2709 to supply either reconstructed sample  $s'_r(k)$  or the noise signal to the digital line interface (DLI). Specifically, when the operate signal is true, the reconstructed sample  $s'_r(k)$  is supplied via

15 multiplexer 2708 to the corresponding DLI and when the operate signal is false, the noise signal is supplied via multiplexer 2708 to the corresponding DLI.

Claims

1. Apparatus for measuring packet delay in a network node, the packet including a header having a time stamp field, the apparatus  
5 CHARACTERIZED BY  
means (119) for generating a local time signal,  
means (208) for generating a packet originate time value referenced to said local time signal value  
10 upon the packet entering a network node,  
means (208) for inserting said packet originate time value in the packet header time stamp field, and  
means (1109) for generating an updated time  
15 stamp value from said packet originate time value from said packet header time stamp field and the local time value upon the packet exiting the network node.
2. The apparatus as defined in claim 2  
CHARACTERIZED IN THAT  
20 said means for generating said packet originate time value comprises means for obtaining the difference between the local time signal value upon the packet entering the network node and a time stamp value from the packet header time stamp field.
- 25 3. The apparatus as defined in claim 1  
CHARACTERIZED IN THAT  
the network node is a packet originating node and wherein said means for generating said packet originate time value comprises means for setting said  
30 packet originate time value to the value of the local time signal at the time that the packet is originated.
4. The apparatus as defined in claim 2  
CHARACTERIZED IN THAT  
said means for generating said updated time  
35 stamp value comprises means for obtaining the difference between the local time signal value upon the packet exiting the network node and the packet originate time

0234860

value from the packet header time stamp field.

5. The apparatus as defined in claim 4  
further

CHARACTERIZED BY

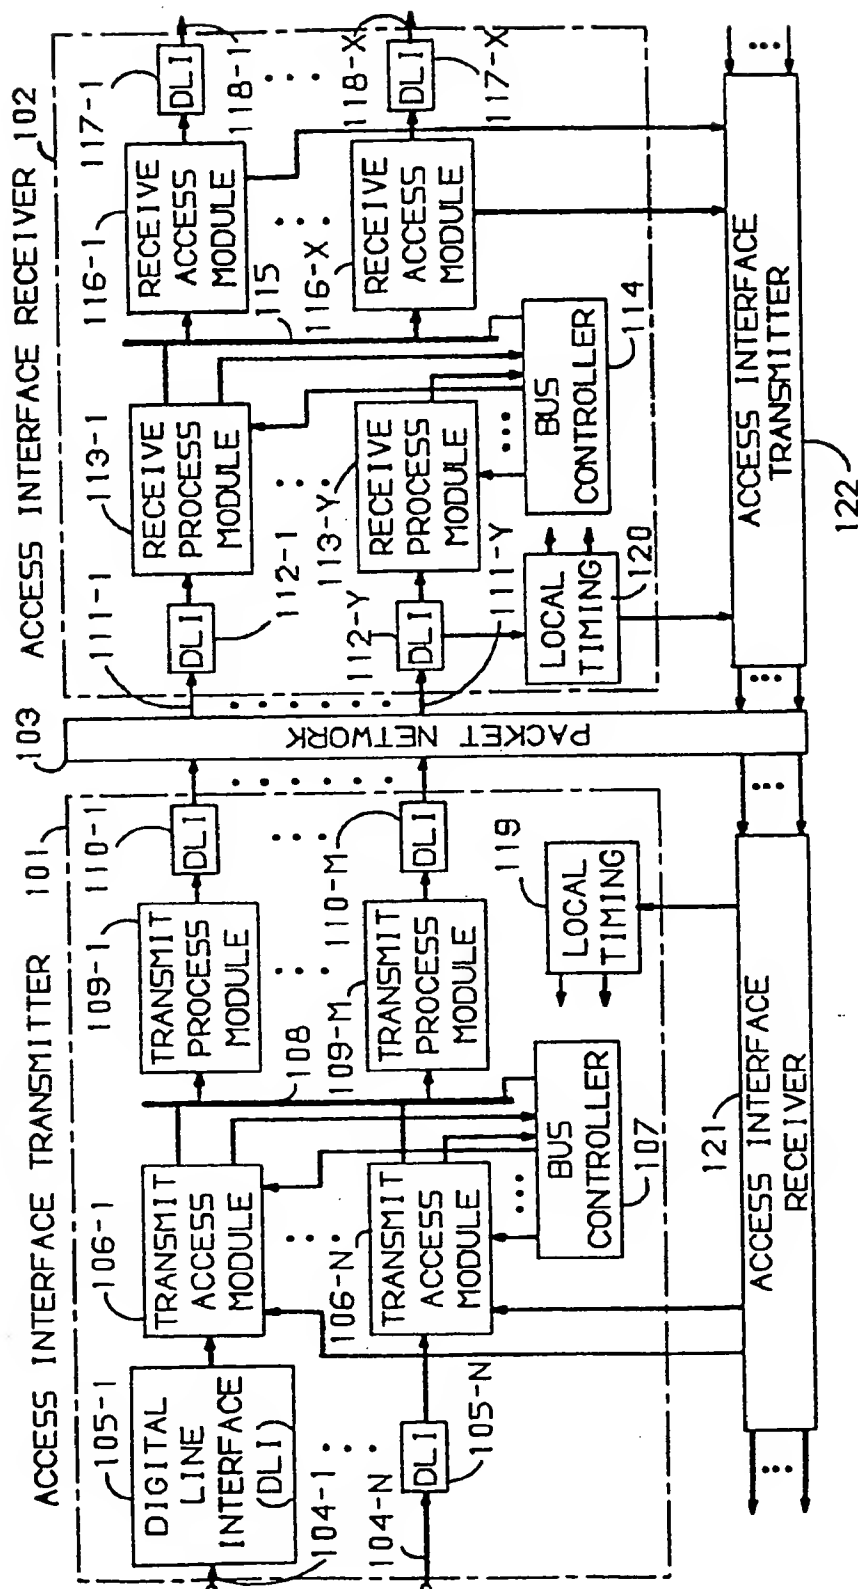

5 means for inserting said updated time stamp  
value as the time stamp value in the packet header time  
stamp field.

6. The apparatus as defined in claim 8

CHARACTERIZED IN THAT

10 said means for generating said local time  
signal generates said local time signal for obtaining  
said packet originate time value and for obtaining said  
updated time stamp value.
